PREFACE

The first two editions of *The Encyclopedia of Creativity* were enormously successful. They provided easily-accessible and trustworthy information about creativity and various topics related to creativity, such as innovation. The second edition, published in 2011, was named a 2012 *Outstanding Academic Title* by the American Library Association's Choice publication. The 3rd edition was inspired by the vast amount of new research about creativity. The field is expanding very rapidly. Much of this research is related to the increased complexity of each of our lives. Creativity helps each of us deal with such complexity. It also helps businesses, schools, and other organizations as the demands placed on them move faster and becomes more urgent. In addition, creativity provides new answers to such difficult problems as climate change, limited resources, religious and territorial conflicts, and poverty. For these reasons the *Encyclopedia of Creativity* includes articles that describe the creativity of individuals as well as organizations.

The *Encyclopedia* captures the full range of approaches to creativity. Creativity research is being conducted throughout the world in many different disciplines, including psychology, arts and humanities, health sciences, education, and business. The global interest is reflected in the number of authors throughout the world who have contributed to this edition as well as the topics covered.

Some countries such as China, Korea, Singapore and New Zealand have made understanding, teaching, and encouraging creativity part of their national goals. Europe proclaimed 2009 the year of creativity. The leaders of these countries recognize that their primary natural resource is the ability of their citizens and organizations to develop new products and innovative concepts. As competition becomes more and more intense, the business community in the United States is finally accepting the concept that creativity can contribute directly to the bottom line. A poll of CEOs in the United States by IBM's Institute for Business Value indicated that creativity is the most important characteristic being sought in new executive hires. We have responded to the increased interest in the business community by including more entries on organizational creativity.

The *Encyclopedia of Creativity* is designed to inspire further recognition of the personal as well as professional benefits that accrue from encouraging creativity. We know, for example, that individuals who are more creative are healthier and more adaptive, and in some instances may even have a longer life expectancy. We also know that many innovations and ways of solving problems have already led to incredible benefits, such as cures for diseases, improved technologies, and higher living standards for billions of people.

If we want a more creative world, then we must construct an environment that allows creativity to flourish. This requires knowledge that crosses disciplines. The increased quantity and diversity of research continues for the most part to be focused on a specific area of interest. Most scientific research is still released only in academic journals. There is still not a broad cross-fertilization of knowledge that enhances the development of new ideas. One of the axioms in creativity research is that breakthroughs often occur when information or concepts from one field are applied to a different one. Darwin's theory of evolution was partially inspired by his reading Malthus' theory of population growth and Lyell on geological change. Jean Piaget, noted developmental psychologist, borrowed heavily from biology and epistemology. Freud used a medical model to understand the psyche. Our hope is that readers will roam outside their usual areas of interest in a search for new ways of thinking. The comprehensive nature of the encyclopedia offers readers the opportunity to find new perspectives, which we hope will suggest fresh insights about themselves, their work, and their place in the world.

In the first edition we stated that there was enough known about creativity that it could be integrated into every level of our educational system. Unfortunately "teaching to the test" has become more prevalent in the United States while arts programs have been all too often dropped. We are obviously losing a great deal of the creative potential on this planet by leaving so many of our children uneducated and unable to cope with the

problems they face. The Encyclopedia continues to place an emphasis on education and cognition. It is our hope that teachers at the elementary and high school level will learn about their own creativity and how to value and encourage students. It is not always an easy task, but it can help enhance and even save the lives of some creative students who are at risk.

There has been some progress. The increased recognition of the importance of creativity in education was exemplified by its inclusion as number 8 in the top 20 competencies for teachers by the American Psychological Association. A 2019 Gallup poll in the United States reported that “Eighty-seven percent of teachers and 77% of parents agree that teaching approaches that inspire creativity in the learning process have a bigger payoff for students.”

Improvement is also evident at the college and post-graduate levels where courses in creativity are taught in many schools throughout the country. There is still a tremendous need for degree earning programs and specializations in creativity. The Torrance Center at The University of Georgia, Saybrook University, Buffalo State, and Drexel University are among the schools that currently allow a specialization in creativity studies. We hope that soon there will be many more universities and professional schools which include courses and specialties in creativity studies.

Audience

This Encyclopedia was designed for use by students of creativity, as well as researchers, teachers, scientists, coaches and consultants, architects and designers, trainers, managers, actors, writers, directors, painters and other individuals in the creative arts, inventors, therapists and other professionals who utilize creativity in their work. Anyone who is interested in learning more about their own creativity and the creative process can benefit from the articles presented here. None of this implies that there are quick and easy self-help answers - individual creative growth requires work, time, serious thought and a commitment to deeper understanding of the process. Still, creativity can be fun and it adds to the quality of life. Creativity can help us experience the highest levels of involvement in work and play that ultimately leads to great joy. Readers are encouraged to follow their own interests and inclinations in exploring these volumes.

Topics and Contents

Creativity is often viewed as a syndrome or complex. This perspective is described in various contributions to this volume, as are the various processes that are thought to make up or contribute to creativity. Other entries focus on particular methods and disciplinary approaches. In fact, one significant difference between this edition and the last one is that of sections devoted to the neurosciences and to technology and creativity. In addition, this edition is organized as a kind of hybrid, with overarching topics, including the two just mentioned, but also with various articles subsumed under Measurement and Personality headings. Specific topics include the following:

- There are reviews of a number of domain-specific areas, such as acting, dance, expressive arts, film, food, music, religion, science, sports, theater, and writing.
- Creativity and education are examined in articles about thought processes, such as developmental trends in creative abilities and potentials, the enhancement of creativity, intelligence, knowledge, play, prodigies, programs and courses, talent and teaching creativity.
- Cognitive aspects of creativity can be investigated in articles about altered and transitional states, analogies, attention, cognitive style, divergent thinking, flow and optimal experience, metacognition, metaphors, problem-finding, problem-solving, and remote associates.
- Those interested in business and organizational creativity can view articles about advertising with art creative visuals, business/management, creativity coaching, creativity exercises, entrepreneurship, group dynamics, innovation, leadership, organizational culture, organizational development, teams, and training, among others.
- Many articles examine the creative process across domains including areas such as discovery, emotion/affect, gender differences, incubation, inspiration, insight, novelty and paradigm shifts.

- The complex interrelationship between society and creativity is explicitly examined in articles about awards, conformity and conventionality, the creative sector and class of society, cultural diversity, the dark side of creativity, East vs. West, networking, social psychology, war, zeitgeist, and others.
- Personal and interpersonal creativity is discussed in articles relating to collaboration, family, life stages, mentors, networking, personal creativity and self-actualization.
- Because the encyclopedia focuses on scientific information about creativity, there are also articles that discuss concepts of creativity, definitions of creativity, expertise, longitudinal studies, researching art, artists and art audiences, research methods, phenomenology research and qualitative research.
- Articles which look at theoretical perspectives include behavioral approaches, chaos theory, componential models, economic perspectives, the evolving systems approach, the four P's of creativity, and implicit theories.
- The creative process is examined in contrarianism, climate for creativity, discovery, dreams, heuristics, invention, motivation/drive, multiple discovery, novelty, time and rewards.
- Mental and physical health and creativity are reviewed in mental health: affective disorders, health, mad genius controversy, schizophrenia and psychosis, stress, suicide, and transforming illness and visual art.
- Some subjects are grouped together in the Table of Contents. These clusters include the increasingly important Neurosciences and Technology, as well as Personality and Regional Creativity.

More than any other kind of book an encyclopedia is a collaborative effort. We thank our eminent panel of Subject Editors: Arthur Cropley, Vlad Glaveanu, Ning Hao, Maciej Karwowski, Aaron Kozbelt, Weihua Nui, Roni Reiter-Palmon, and Robert Weisberg.

Actors in any capacity, artists of any stripe, are inspired by their curiosity, by their desire to explore all quarters of life, in light and in dark, and reflect what they find in their work. Artists instinctively want to reflect humanity, their own and each other's, in all its intermittent virtue and vitality, frailty and fallibility.

Tom Hiddleston, www.goodreads.com/quotes/tag/acting.

Acting is an ancient art form that has existed since the beginning of recorded time (Brockett, 1974). The Merriam-Webster dictionary defines “act” as the process of doing something, “acting” as the art or practice of representing a character on a stage or before cameras, and “actor” as one who acts in a play, movie, television show, etc. The process of acting involves the willingness of an individual to represent a character in order to tell a story. Highly trained and skilled actors embody the character so completely that the audience forgets that they are watching an actor portray a character. The story unfolds and the audience willingly suspends their disbelief as they witness the “reality” of the depicted story.

The revolutionary moment when acting was forever changed occurred when Thespis stepped away from the Greek chorus and proclaimed to the audience that he was the god, Dionysus. He was not only claiming to be someone else but he was also stating that he was a god. This decisive moment shaped how actors tell a story (Brockett, 1974). No longer did they merely report the myths or legends of the time, they now assumed the roles and gave life to the events of the story.

Acting is a complex topic that is influenced by cultural diversity, economic constraints, and lifespan demands. In this entry, topics include the creative process, in particular, character development, training criteria, memorization requirements, and the re-iterative gene-lore process. The challenges associated with talent identification, the collaborative nature of acting, and sustaining a career are outlined. Recent research findings in the fields of physiology, neurobiology, and psychology are incorporated to identify factors that are specific to actors and acting. Although not discussed directly, “Lady Luck” is always at play in the career of any actor. Synchronicity and spontaneity often guide the trajectory of an acting career as well as engaging in training and the creative process.

In order for acting to take place, a collaborative group of people are typically involved in a distributed creation of a new work (Sawyer and DeZutter, 2009). Some of the many members of this team include writers (playwrights and screen writers), directors, producers, artistic staff and designers (costume, lighting, sets, props, composers, choreographers), marketing and publicity personnel, technical directors, crew (backstage, front of house, camera operators, editors, sound technicians), talent agents and managers, and always the actors. Today, acting can be witnessed live in a myriad of venues (i.e., Broadway, concert halls, black box theaters, outdoor venues, comedy clubs, improv clubs) or digitally in the media arts (i.e., film, television, radio, Internet, mobile technologies, video games). Beyond the large number of people who are directly or indirectly involved in the creation of a performance, an even larger number of audience members view the event. According to the 2012 statistical data collected by the National Endowment for the

Arts, the majority of the American population viewed a media product (i.e., television, radio, online platforms), 71% viewed acting as part of the Internet, and 45% attended at least one live theatrical event. In total, these figures surpass the 30.4% of the US population that attended an amateur or professional sporting event. Acting has a vast influence on daily life; even if viewers are unaware they are witnessing acting (i.e., commercial advertising, reality media programming, docudrama).

Creative Process and Acting

Actors are regarded as creative artists in their own right; however, they are also interpretive artists. They must give life to a script, further the action of the plot, and remain faithful to the character they are portraying. The majority of actors are highly trained, often within recognized acting systems (Hodge, 2000). They must train their body, their voice, and their emotional expressivity in order to inhabit the role of a character. As well, they develop powerful memory retention skills. In order to enhance memorization skills, actors learn to converge visual and linguistic feedback (Palmiero et al., 2010). The combination of physical posture and gesture, vocal intonation and enunciation, entering intense emotional states and transforming these states, and actively listening and responding to other actors and the audience are all operational in every moment that an actor is performing. The goal is to integrate and inhabit these elements without conveying to the audience any of these variables. Actors must also remain faithful to the text and the intention of the writer, while affirming their commitment to the portrayal of the character and sustaining immediacy with the text, the other actors, and the audience (Hodge, 2000).

The creative process in acting involves several phases that generally remain consistent, although it may vary slightly depending on the medium and project. Often described with slight wording variations, the three phases include the initial interaction with the project, the script, and sometimes the cast, followed by a rehearsal phase that may vary in length, and finally, the performance phase. The rehearsal phase involves the most complex process. The character must be understood and personalized, including outlining character objectives, needs, actions, and trajectory. The text must be analyzed and memorized and the character must be embodied (vocally and physically). Stage or camera blocking (pathways and focus) must be established and scenes must be organized and directed. During the rehearsal process creative engagement by all involved is essential.

The creative team, including the actors, participates in the geneplore model of creativity. This two-phase creative model involves a reiterative process of shifting between the generative phase where new ideas emerge from memory retrieval, mental synthesis, and transformation and the exploratory phase that involves an analysis, appraisal, and modification of ideas that are generated (Sternberg, 2005). This creative process may occur in only a few rehearsals or persist for a protracted period of time such as during the creation of new shows that will eventually be produced and performed on Broadway. What remains unique in acting is that the geneplore creative process occurs both individually within the actor and distributed collaboratively amongst the many participants involved in creating the production (Sawyer and DeZutter, 2009).

In the acting studio or rehearsal hall, creativity is enhanced when there is a mixture of structured and unstructured activities (Sowden et al., 2015), such as when a scene is analyzed followed by a brief unstructured improvisational exploration. The combination of both processes promotes cognitive fluency, originality, divergent thinking, self-confidence, and motor creativity (Sowden et al., 2015). Because acting is a collaborative art form, members of the team share their observations and offer suggestions. Critical appraisal becomes a constraint and a source of inspiration (Gibson and Mumford, 2013). The collective ability to examine the work that is emerging furthers the generative and exploratory creative process. In order to manage self- and other-evaluations, a sense of trust and compassion must be nurtured in the studio and rehearsal hall (Seton, 2010). Without these two factors, creativity is dampened while trait and state shame-prone withdrawal and ruminative self-criticism may escalate (García et al., 2017).

Identifying and Developing Acting Talent

Actors frequently remember a childhood that was filled with imitating others, role-playing popular characters, and creating imaginary worlds (Goldstein and Winner, 2009). These activities may be the fertile ground that nourishes absorption, persistence, discovery, and synthesis; all components of creativity. Young actors also demonstrate a natural talent to memorize texts and acquire a growing awareness of the impulses and intentions of others, in particular, for the characters that confront obstacles within the imaginary scenes they create or the scenes that they have memorized (Goldstein and Winner, 2009). During these early explorations in acting, the young actors also acquire a stronger theory of mind (awareness that the other has a separate mind), as well as a more empathic understanding of the suffering of others (Nettle, 2006). Many actors pursue a career in acting despite a lack of parental support or understanding (Goldstein and Winner, 2009; Kogan and Kangas, 2006). Their early interests inform their later career aspirations, including seeking training at an older age in order to realize their goals (Rasmussen and Rasmussen, 2015).

Actor training must include educating the imagination, especially training skills to sustain mental and emotional imagery (Hodge, 2000). Regardless of the actor tradition (i.e., Stanislavski, Hagen, Suzuki, Bogart, Meisner), actors are trained to explore their imagination, generate novel ideas, probe their emotional or sense memories, and investigate embodied processes related to the character and the circumstances that the character experiences (Hodge, 2000). In order to meet the intense physical and emotional range of many characters, actors must cultivate physical, vocal, and psychological skills. Emotional states are expressed through vocal intonation, tempo, pitch, loudness, articulation, and vocal quality. Actors learn to project and modulate their voices to enliven emotional expressivity; without years of vocal training actors are vulnerable to vocal disorders which can shorten or

compromise their careers (Master et al., 2008; Walzak et al., 2008). Movement classes, martial arts, stage combat, alignment work (i.e., Alexander Technique), and improvisation all enhance physical expression, and dramatic intention is developed in script analyses, improvisation, and scene work classes. Often during acting training, especially during script analyses and actively embodying the character, actors learn to empathize with the character to be performed (Hodge, 2000). They must remove personal moral judgment and embrace all that has influenced the character.

In all training settings, student actors are profoundly influenced by positive and negative teaching methods and by the ethical practices that operate in the training organizations (Seton, 2010). Some of the key positive factors that enhance actor training include an environment that fosters trust, respect, freedom, challenge, collaboration, and clarity (Seton, 2010). Cultivating an ethically respectful environment is even more vital given the reality that many actors enter formal training much later than musicians or dancers; in part, because actor training requires a complex multidimensional approach necessary to portray complicated characters who exist in adverse situations; this frequently requires more developmental maturity (Kogan and Kangas, 2006). Generally, acting programs are effective in this training; however, there are currently too many highly trained actors given the limited professional opportunities (Wilkie, 2015). In an effort to ameliorate this situation it has been proposed that curriculum in acting training programs now include courses in psychological self-regulation and entrepreneurial skills that can extend beyond an acting career (Wilkie, 2015).

Physiologic and Neurological Demands of Acting

The demand of embodying a character involves the actor's neurological and physiologic systems. The complex vocal, physical, and emotional requirements of acting are reflected in the biology of the actor. For example, actors exhibit higher physiologic responses when expressing emotional states of the character compared to untrained performers (Pelletier et al., 2003). Their heart rate and autonomic (sympathetic) nervous system responses are intensified when they express anger, disgust, fear, and happiness. Neurologically, actors have more integration in the vocal-motor and sensorimotor neural networks. Through training, actors can discriminate and decode pitch in verbal discourse and they can differentiate task-relevant and task-irrelevant auditory and visual signals (Pelletier et al., 2003). They develop auditory-motor expertise. Because they also express a full range of heightened emotions, they rapidly access emotional neural circuits that are integrated in the implicit motor neural circuit and the subcortical and cortical regulatory networks (Pelletier et al., 2003).

Vocal training also provides unique physiologic changes in actors. Compared to untrained actors, professional actors demonstrate greater vocal fitness and enhanced respiratory capacity. They also have lower pitch as a result of vocal training (Master et al., 2015). In addition, language and action are more deeply integrated within the cortical and subcortical regions of the brain (Pelletier et al., 2003). In part, this is related to the complex vocal, physical, and emotional training, as well as the constant demands to memorize large quantities of dialogue. In addition, greater integration is evidenced in regions in the brain responsible for attention, attentional shifting, and social-emotional understanding (Pelletier et al., 2003).

Psychological Elements

Personality studies that examine actors reveal a wide range of traits, which are often contradictory. For example, actors manifest greater extraversion, openness to experience, adventurousness, expressiveness, agreeableness, dogmatic behavior, aggressiveness, impulsiveness, sensation seeking, ambition, reflective thinking, mystical beliefs, risk-taking, irresponsibility, neuroticism, and guilt-proneness (Kogan and Kangas, 2006; Nettle, 2006). Beyond personality investigations, studies have demonstrated that actors have a greater family history of mental illness and addiction (Baker, 2008). As well, the unpredictable nature of an acting career is often associated with increased incidences of illness, including substance abuse and stress related illnesses (depression and anxiety). For example, in Great Britain, actors were classified as the third highest profession to die from these disorders (Baker, 2008).

When portraying a character, many actors experience a blurring of the character's identity with their own identity. Despite excellent training, the actor inevitably experiences the visceral life of the character, even if it is for brief moments during a performance (Burgoyne et al., 1999). Self-perceptions are altered during the course of a performance, and even more so during long performance seasons. For many actors, they experience greater empathy and social cognition for their character (Nettle, 2006), which may intensify identity boundary blurring. As well, actors tend to employ more dissociative processes (absorption and compartmentalizing), which increase potential character boundary blurring (Thomson and Jaque, 2011). Actors also experience more unresolved mourning for past trauma and loss experiences, in part, because they continually draw from these experiences when portraying characters (Thomson and Jaque, 2012). Adding to this tendency to merge with the creative work, audience members also confuse the character's personality with the actor's personality (Tal-Or and Papirman, 2007). Audience attribution errors may increase distress in the actor, including fearing that their personality identity is not stable.

For some actors, there is a tension between their moral values and those of the character, and yet they must sublimate their own moral abhorrence in an effort to portray the character without judgment (Hodge, 2000). It is the task of the audience to determine a moral stance related to the actions of a character. This is ultimately the goal of good storytelling. Developing a performance work that can shape or change the moral values of an audience is inherent within many productions. This was demonstrated in a research study that investigated the effects of musical theater and how it changed audience's attitudes (Heide et al., 2012). Likewise, students

who are exposed to theatrical productions frequently exhibit greater academic achievement and future career success (Catterall et al., 2012). They are able to internalize how characters face conflict and seek solutions.

Child actors present with added psychological complications. They often spend long hours on film or television sets or in rehearsal halls and theaters. They are exposed to public scrutiny, which may intensify identity confusion, especially when audiences misattribute the character's personality with the child (Tal-Or and Papirman, 2007). Parent-child relationships are altered including the reality that the child actor is frequently removed from the complexity of a nurturing family environment (Anderson, 2011). These young actors are at increased risk of developing a weaker self-concept and poorer emotional regulation (Anderson, 2011).

Regardless of the age of actors, when they are required to perform traumatic testimonial-based material, many are troubled by past trauma or vicarious trauma-related symptoms (Thomson and Jaque, 2011). Effective acting training offers tactics to navigate this difficult material. For example, actors are encouraged to implement higher cognitive processing as well as reduce their tendency to personalize the traumatic material. Distancing emotionally from the character must be encouraged during rehearsals and following performances (Burgoyne et al., 1999; Thomson and Jaque, 2017). As well, adopting a positive stance regarding the inherent meaning contained within the creative work supports a sense of self-efficacy, meaning, and resilience.

Sustaining a Creative Career in Acting

Social influences (i.e., social support, talent mentoring) can undermine or enhance an actor's performance and career trajectory (Nettle, 2006). As well, the demand of the production influences the mood and self-efficacy of actors. Actor personalities also influence project preferences; actors who seek high-risk activities are typically drawn to more action-based works whereas introverted actors may explore more emotionally dark pieces. These career choices are based on mood-congruent selections (Wilhelm et al., 2004). Another factor that encourages a career in acting is the positive rewards during flow states. Many actors, and their audiences, recognize these transformative states, especially when the challenge of the work is met with adequate skills and the feedback during the performance is unambiguous and direct (Robb and Davies, 2015). Whether actors work continuously or intermittently, their career satisfaction is much greater than their job stress (Wilhelm et al., 2004). They value opportunities to explore new works, including experiencing a sense of autonomy and self-determination.

Conclusion

Acting is a creative process that integrates multiple factors. It requires substantial training and preparation in order for actors to work with a sense of spontaneity. Acting is also a collaborative art form. The creative process of acting requires actors to strongly engage with the text, other actors, directors, designers, and crew (media or theater). Historically, Stanislavski is recognized as a titan in the field; he changed the landscape of acting, including what an audience expects from a performance. Today, it is understood that actors must portray an authentic character, one that is always emotionally and physically engaged. The immediacy of acting necessitates that the actor is "present" in every moment. This tradition actually was born when Thespis courageously stepped away from the Greek chorus to assume the role of Dionysus. The Greek audience also joined in this mercurial creative process; they "believed" that Thespis was Dionysus. This same delicate process continues. The creative process of acting is rooted in the power to give life to characters and share stories and situations experienced by these characters. Actors and audiences collectively join in this process, one that enriches all our lives.

Glossary

Conceptual Expansion A type of creative thinking that involves loosening the structure and definition of acquired concepts.

Divergent Thinking A type of creative thinking that involves generating multiple ideas or solutions from a single starting point.

Enhanced Perceptual Processing (EPF) EPF is an account of the enhanced perceptual processing in individuals with ASD; according to EPF theory, individuals with ASD have superior low-level perceptual operations and representations.

Inhibitory Control An executive control process that enables one to suppress or regulate prepotent (i.e., strong or automatic) responses to stimuli; enables one to focus on relevant stimuli in the presence of irrelevant stimuli.

Savant/Savant Syndrome A savant (individual with savant syndrome) is someone with general cognitive impairments but exceptional ability in a domain such as music, drawing, or calculation.

Repetitive Transcranial Magnetic Stimulation (rTMS) TMS is repetitive non-invasive stimulation of the brain. An electromagnetic coil is placed on the scalp to deliver an electric current to a specified region of the brain leading to either increased or decreased activity in the targeted region.

Underconnectivity Hypothesis The underconnectivity hypothesis proposes that underconnectivity between posterior and anterior brain areas may underlie ASD symptoms.

Weak Central Coherence (WCC) WCC is an account of the enhanced perceptual processing in individuals; according to WCC theory, individuals with ASD have a deficit in global processing that leads to greater focus on low-level perceptual information.

Introduction

Attention Deficit Hyperactivity Disorder (ADHD) and Autism Spectrum Disorder (ASD) begin in early childhood and persist into adulthood. They have neurological bases and distinct profiles, but do share certain cognitive characteristics such as attentional impairment. In addition, studies suggest that both of these developmental conditions may be associated with enhanced creativity. However, this manifests differently in each population.

The evaluation of creativity, creative cognition and achievement in ADHD and ASD individuals is highly variable between studies, which may contribute to the mixed findings in the empirical literature. Measures include assessments of actual (real-world) creative achievement, laboratory design tasks (e.g., inventing new toys, product labels, or cell phone features), creative activities such as collage making or storytelling, and standardized measures of creative ability, such as the Torrance Test of Creative Thinking, or TTCT.

The TTCT emphasizes divergent thinking; a mode of cognition marked by expansive thought and the generation of multiple ideas or solutions, and includes verbal activities (e.g., list possible outcomes in a hypothetical situation) and figural/visual activities (e.g., drawing multiple pictures from a simple shape or line). Similarly, the unusual (or alternate) uses task requires one to list multiple possible uses for a common object such as brick. Divergent thinking tests are typically scored for: fluency

(number of responses), originality (uniqueness of responses), flexibility (categorical fluency or shifts), and elaboration (level of detail). Standardized tests like the TTCT also yield a composite score and optional scoring for creativity indicators such as richness of imagery, emotion, and fantasy. The latter dimensions may be more sensitive to individual differences than global or composite indices.

Other aspects of creative cognition, such as conceptual expansion, have been evaluated using tasks borrowed from mainstream creativity research. Overall, the diversity of methods reflects a trend toward a more fine-grained analysis of creative strengths in ADHD and ASD, rather than global assessment of creative ability or performance.

Attention Deficit Hyperactivity Disorder

ADHD is a complex disorder, characterized by irregularities in attention, impulse control, and motor activity, which begins in childhood and persists into adulthood. For many individuals with this condition, ADHD creates difficulties in school, work, and social situations. Yet, a growing body of evidence suggests that individuals with ADHD may also be exceptionally creative. Hints of an ADHD-creativity connection arose in the 1970s, when children diagnosed as ‘hyperkinetic’ were evaluated by researchers at the Foundation for Gifted and Creative Children. The children had been referred to the clinic by their parents, who were concerned that educators were mistaking the children’s creative behavior for hyperactivity. The evaluation of this particular group of children showed them to be similar in creativity to children referred to the clinic for reasons other than disruptive behavior. Yet, anecdotal reports of higher creativity among ADHD children continued to surface, and these inspired empirical investigations.

Creativity in Children With ADHD

Early studies of the ADHD-creativity connection compared gifted (high IQ) children with ADHD and their non-ADHD/high IQ peers on standardized measures of creative ability. This research found higher overall creativity, originality, and flexibility for children with ADHD, relative to non-ADHD children, on visual activities. Moreover, the creativity of the ADHD children was linked to their ability to incorporate peripheral environmental information into their figural creations. Among children of average intelligence, those with ADHD performed similarly to non-ADHD children on standardized measures of creativity, which led to speculation that high intelligence was necessary to enable children with ADHD to use poorly filtered information for creative purposes. Yet, later studies of average-intelligence children revealed ADHD-related creative strengths in specific qualitative dimensions of visual creativity, such as expressiveness of ideas and richness of imagery. Similar findings have been reported in research of creative storytelling: children with ADHD told stories that were higher in originality and elements of fantasy—yet shorter (lower fluency)—compared to children without ADHD. Children with average intelligence and ADHD also show selective advantages in creative generation tasks. In one such study, children with ADHD demonstrated higher novelty on a toy invention task relative to their non-ADHD peers (Abraham et al., 2006).

Children with ADHD share a number of traits with children who are intellectually and/or creatively gifted; characteristics ascribed to both groups include high energy, curiosity, artistic, impulsive, hyperactive, and argumentative. Teachers may be more likely to label creative children as disruptive and inattentive, and children who are highly creative may be misdiagnosed as ADHD. At the same time, a child may be both gifted and diagnosed with ADHD. The question of whether children with ADHD are more creative than non-ADHD peers is not straightforward, and findings are mixed. Overall, studies of children suggest that ADHD is positively linked to specific aspects of creative thinking, such as originality and expressiveness of ideas (See Children’s Creativity).

Creativity in Adults With ADHD

In recent years, the scope of research has expanded to encompass adults with ADHD. Generally speaking, adults and children with ADHD show a similar pattern of creative strengths. In studies of college students, those with ADHD show higher originality than non-ADHD peers on divergent thinking tests (unusual uses task) as well as realistic creative design tasks (White and Shah, 2016). College students with ADHD also demonstrate selective advantages on aspects of standardized creativity tests; in particular, ADHD is associated with higher originality, expressiveness of ideas, richness of imagery, and elements of fantasy. Like children with ADHD, adults also show lower conformity to task examples in creative generation tasks; and, adults with ADHD are less constrained by prior knowledge on tasks of conceptual expansion.

Adults with ADHD may have a more chaotic creative approach than non-ADHD adults, as evidenced by a relatively high preference for the idea generation stage of creative problem solving and a tendency toward divergent, original thinking (White and Shah, 2011). In contrast, non-ADHD individuals may be more likely to engage in structured creative cognition. For example, if asked to invent an animal or fruit that might exist on another planet, most people would start by thinking of a typical animal or fruit on Earth and then modify it somewhat into an “alien” version. An artifact of this process of structured imagination is persistence of features of the inspiration in the creative product; as a result, the creation may be lower in novelty and originality. Likewise, imagination may be limited by the imposition of categorical regularities; for instance, a person creating an alien creature might include the property of bilateral symmetry, as this is typical of animals on Earth. Studies have shown that adults with ADHD are less likely to be constrained

by recently presented and prior knowledge during creative generation. Moreover, adults with ADHD are more likely to engage in conceptual expansion—the process of extending categorical boundaries and conceptual structure— compared to non-ADHD adults (White, 2018).

Explanatory Models of Creative Cognition in ADHD

Several candidates have been proposed to account for the higher creative cognition observed in children and adults with ADHD. Most notably, these include the core features of ADHD; distractibility and poor inhibitory control. ADHD-related distractibility has been linked to functional irregularities in the default-mode network (DMN), a set of neural pathways and structures that are more active when the brain is not occupied by a goal-oriented task. During focused activity, the DMN is suppressed. Symptoms of ADHD have been linked to interference from the DMN, which has also been dubbed the ‘imagination network.’ In particular, distractibility has been cited as a factor in reduced susceptibility to the constraining effects of knowledge during creative generation observed for children and adults with ADHD.

Low inhibitory control has been linked to original, divergent thinking in non-ADHD individuals, and is likely a contributing factor to ADHD-related creative cognition as well. A primary task of inhibitory control is to restrict the flow of excess and/or potentially interfering information into working memory; therefore, an abundance of information - such as might arise when the gating mechanism is inefficient - could potentially yield fruitful and unexpected combinations.

Evidence for this comes from studies of gifted children with ADHD, which linked visual divergent thinking in ADHD children to their use of peripheral information from the environment for creative purposes (Shaw, 1992). Studies of college students with ADHD also demonstrated a link between poor inhibitory control and higher original thinking among individuals with ADHD (White and Shah, 2006). Low inhibition is also likely to be a factor in the wide semantic activation and breadth of attention observed in adults with ADHD, which have been linked to higher flexibility in realistic creative design activities. Poor inhibitory control may play a role in the lesser constraints of knowledge in ADHD, and the resultant conceptual expansion observed for individuals with ADHD.

In addition to the cognitive processes described above, motivation may also be relevant to creative cognition in ADHD. Models of behavioral dysregulation in ADHD posit irregularities in motivational and reward pathways of the brain. Yet, individuals with ADHD show heightened sensitivity to reward and greater interference control in rewarding contexts. Intuitively, individuals with ADHD should be expected to be most creative when both intrinsically and extrinsically motivated. This hypothesis is supported empirically by findings of higher originality for ADHD students, relative to non-ADHD peers, under reward-seeking conditions (Boot et al., 2017). Personality traits, such as novelty-seeking and openness to experience, may also contribute to real-world creative behavior in individuals with ADHD (See Motivation).

Practical Implications & Creativity in Real-World Contexts

The creative cognition observed in laboratory studies of individuals with ADHD may have real-world implications, as well. When individuals look to a prior model for inspiration, they may become stuck: designers refer to this as “fixation.” Over-reliance on task examples and prior knowledge reduced originality of creative products, yet individuals with ADHD are less constrained by task examples and prior knowledge on creative generation tasks such as invention of new toys or product labels. The creative ideas of individuals with ADHD may thus be less likely to conform to previous models and more likely to thwart conventional structure and expectation.

Creative cognition is predictive of actual creative achievement, which bodes well for the possibility that the creativity of ADHD individuals in the laboratory will manifest in real-world creative behavior. In fact, studies found higher levels of self-reported creative achievement for college students with ADHD compared to non-ADHD students— especially for those domains which aligned with expressed interests. In other research, adults with ADHD endorsed relatively high preference for idea generation in a creative style inventory; taken together, findings suggest that people with ADHD might excel in fields that emphasize brainstorming and creative ideation. ADHD symptoms of impulsivity and hyperactivity were positively correlated with entrepreneurial orientation and intention— and may be a factor in entrepreneurial firm success. ADHD characteristics such as risk-taking may play a role in the success of adults with ADHD in enterprising contexts such as small business startups.

Summary of Creativity in ADHD

Overall, there is growing empirical support for anecdotal claims of a connection between ADHD and creativity. In particular, ADHD may be associated with original, divergent thinking; and, there is some evidence that this may translate into real-world creative behavior. Findings of higher creativity related to ADHD have been more consistently found in studies of high-functioning individuals, such as gifted children and college students. Further research is necessary to determine the precise nature of the relationship between ADHD and creativity, and to identify the factors which may promote the success of individuals with ADHD in real-world creative endeavors.

Autism Spectrum Disorder

Autism spectrum disorder (ASD) is a developmental condition that is associated with impaired communication and behavior. Specifically, individuals with autism have challenges communicating and interacting with others. They sometimes display unusual or repetitive behaviors. Furthermore, they often have highly restricted interests in certain domains like numbers or art. ASD is also associated with some cognitive strengths in that people with ASD encode and remember visual and auditory information with precision.

Empirical Studies of Creativity in ASD

Research on creativity in ASD is mixed, with individuals that have ASD often showing lower or equivalent levels of verbal divergent thinking on the unusual uses task and standardized measures, such as the TTCT, compared to the general population. On figural divergent thinking tasks, however, individuals with ASD may create drawings higher in originality and elaboration, relative to non-ASD peers. Yet, ASD participants may score lower in flexibility, because they frequently draw figures associated with their primary interests (Liu et al., 2011). In another study, amongst a non-clinical sample, autistic traits were associated with lower fluency and higher originality of divergent thinking (Best et al., 2015). Across these studies, it seems that individuals with ASD may approach tasks of this sort with a more narrow focus on a few domains of interest, and thus show lower fluency and flexibility; at the same time, they elaborate upon each idea generated and many of these ideas are original relative to the general population.

Savant Syndrome and Creative Talent

Despite the lack of evidence for higher creativity on standardized measures, some individuals with ASD show great talent in creative domains such as the visual and performing arts. Indeed, a well-known phenomenon is that of the savant, who may have ASD but also shows special talent in a specific domain. Stephen Wiltshire, for example, is an artist with ASD from the UK made famous by television specials and as one of the subjects in Oliver Sacks' book *An Anthropologist on Mars*. He creates extremely detailed and precise drawings of scenes he has only glanced at briefly; his impressive drawings sell for huge sums and are included in museums and private collections. At the same time, he learned to speak very late in childhood and has substantial deficits in communication, social skills, and cognition. Derek Paravicini is a savant musician but shares traits with Stephen Wiltshire. Just as Wiltshire can briefly view a scene and reproduce it from memory, Paravicini can listen to a musical piece a single time and play it from memory.

The prevalence of savant skills is unclear, in part because of lack of a clear definition of savant. Prodigious talent such as displayed by Wiltshire and Paravicini is rather rare, with perhaps as few as 100 such individuals worldwide who are known to researchers. At the same time, up to 10% of individuals with ASD have some savant abilities that stand out. Estimates for the proportion of ASD individuals who show some special talent (at least relative to their own general skills) is even higher. One study found that as many as 70% of individuals with ASD had some unusual individual skill. Some of the skills reported in that study included calendar calculation, mathematics, and memory. However, 17% showed special talent in drawing and another 17% in music. Another recent study found that parent ratings of autistic traits in children were correlated with ratings of talent. Furthermore, there is an overlap between genes associated with autistic tendencies and genes associated with "talent." Note, however, that this more common "special talent" does not reach a savant-level ability. Furthermore, it is perhaps in the eye of the beholder whether or not these talents lead to truly original products (as opposed to mere mimicking); the selection of subjects, for example, may be unique.

Explanatory Models of Creativity in ASD

There are several possible explanations for the potential creative strengths of individuals with ASD. Two prominent accounts focus on the perceptual processing of individuals with ASD, including the "Enhanced Perceptual Functioning" or EPF theory of Motttron et al. (2009) and the "Weak Central Coherence" or WCC theory of Happé and Frith (2006). Both theories are based on the relative emphasis on lower-level perceptual features/local processing compared to higher-level features/global processing. However, they differ in the extent to which they attribute this bias to superior perceptual processing versus a deficit in higher-level processing. These approaches also differ in terms of the assumptions regarding the underlying neural basis of ASD processing differences and the role of early experience. For example, hypersensitivity to sensory information may impact the development of perceptual representations.

Regardless, there is a great deal of evidence for the local versus global advantage in ASD. On tasks in which global information may interfere with local (such as on the block design task of the Wechsler Adult Intelligence Scale), ASD individuals do better than non-ASD individuals. Likewise, ASD individuals are better at recognizing and copying "impossible" figures and finding "hidden" figures in the Embedded Figures task. Lower-level perceptual and attention tasks also show preference for local processing; ASD individuals, for example, are faster at visual search tasks and less affected by distractors than non-ASD individuals.

One neural explanation for enhanced lower-level perceptual processing and emphasis on local features over global form is lower connectivity across brain regions (e.g., between the frontal lobe and sensory areas) and greater connectivity within regions (the Underconnectivity Hypothesis). Additionally, individuals with ASD show greater activation of low-level perceptual areas (e.g., posterior occipital areas that represent smaller areas of space with less feature integration) and less activation of higher level areas (such as the fusiform face area). The possibility that less top-down frontal influence on perceptual areas may be associated with

savant properties was tested in several intriguing studies using repetitive Transcranial Magnetic Stimulation (rTMS) to suppress frontal activation in non-ASD individuals. Some, but not all, participants in these studies showed enhancements in a variety of skills: drawing with more detail, noticing errors while proofreading, subitizing objects, and having more veridical and fewer false memories.

The relative emphasis on local versus global information, regardless of the neural explanation, is associated with the fact that individuals with ASD may create more precise, veridical representations of one or more perceptual systems (e.g., auditory pitch, visual scenes). Perceptual abilities in turn may serve as the basis of savant strengths. All musical savants have perfect pitch, for example (and non-savant individuals with ASD have better pitch perception and memory than non-ASD individuals).

Individuals with ASD may either have innate lower-level perceptual processing capabilities or may develop these capabilities due to greater attention to certain stimuli. The fact that development and experience may play a role is supported by the fact that people with ASD also show more sensitivity and responsiveness to perceptual stimuli. It should be noted that enhancement of lower-level perceptual processing is associated with related strength in memory for lower-level perceptual information. Nonetheless, the general argument is that quality of perceptual inputs, attention/sensitivity to perceptual information, and high quality veridical memory representations could, together, serve as the basis of savant strengths. Indeed, the characteristics of many savant creative achievements such as the achievements of Wiltshire and Paravicini involve creating striking veridical reproductions of visual or auditory information.

The direct veridical replication of information without creative generation does not seem to be the limit of savant abilities, however. Darold Treffert followed some musical and artistic savants for thirty plus years. He found their initial skills were based on the ability to veridically reproduce music or visual scenes. Over the years, their skills seemed to evolve to be more productive. Leslie Lemke, a musical savant, for example, was initially able to copy full concertos after hearing them only a single time. Later, Lemke began to improvise and play variations of pieces he had heard and then began to compose his own music. Likewise, Stephen Wiltshire can copy scenes exactly as he sees them, yet is also able to create his own original drawings.

While there is considerable support for the idea that perceptual representations are related to savant skills, other characteristics of individuals with ASD may also play a role in talent development. For example, single-mindedness and differences in social functioning may be associated with ASD individuals' motivation to practice. Interest in sorting and taxonomizing various objects may also contribute to savant skills. Wiltshire, for example, shows keen interest in the details of architecture and automobiles. Another artistic savant, Gregory Blackstock, has achieved fame for his elaborate visual taxonomies of animal species, automobiles, and other object categories. Keen interest in the features of objects in the world may help guide savant talent development.

Summary of Creativity in ASD

In summary, individuals with ASD have perceptual and cognitive styles that lead to limitations on some aspects of creativity, such as fluency in divergent thinking. At the same time, these factors are associated with talent in creative domains such as visual arts and music. And, a small number of individuals with ASD show prodigious talent that leads to international renown.

Conclusion: Creativity in ADHD & ASD

In conclusion, there is evidence that both ADHD and ASD individuals have some enhanced skills in creative domains; however, the nature of these differences and their underlying bases are thought to be different.

Many a small thing has been made large by the right kind of advertising

Mark Twain

In every advertising agency is a suite of offices within which people work mainly with “creative” ideas. They have titles such as “Account Planner/Researcher”, “Copywriter/Art Director”, “Community Manager”, “Creative Director”, “Digital Creative Director”, “Digital Copywriter/Art director” or “Designer/Specialist” to name but a few. Yet not everything they produce can be termed “Creative”. Some of it is. Much of it is not. Who can say? Someone might look at an advertisement and say, “wow this is creative!” Yet another person looks at exactly the same piece of work and says: “this isn’t creative at all. How can you say that it is?” The reality is that the extent to which an advertisement, whatever the medium, is creative or not remains a matter of judgment. Some argue that as long as the advertisement “works”, in terms of meeting the objectives of whoever initiated the communication, then why worry? Well perhaps if more people thought it was creative then the advertisement might work even better, grabbing the attention of more people, being more persuasive and thereby effective. This entry investigates what Advertising Creativity is, what makes it effective, how it is developed, and what expertise, processes and structures are important in this development?

Defining Advertising Creativity?

What would make you view an advertisement as creative? One thing would be if it surprised you. You might think, “That’s a strange TV commercial for pizza. I haven’t seen anything like that before. I wonder why they did that and what is it about?” Or you might see a viral post for a car that didn’t look like a normal car advertisement. “What on earth is that about you might wonder” What creativity does is challenge your ideas of the norms. It surprises you and makes you wonder what the communication is about. It might amuse you, make you laugh, challenge your ideas on something, or make you think about a product in a new way. It’s what you might consider an original idea. However, there is a twist. That creative advertisement operated within a confined space. Yes, it was creative, but it was a restricted form. In essence the creative idea was tied to a strategic objective. That objective might be to communicate the quality of the ingredients of the pizza, or the safety features of the car. The creativity was not random: it had a purpose.

To look at this more closely, most current definitions of advertising contain two core elements. Firstly, advertising involves a paid form of message that is largely controlled by an identified sponsor. Second, the aim of this message is to inform and persuade consumers, influencing how they think or act toward the organization’s ideas, products and/or services. Likewise definitions of what constitutes a creative idea usually contain two key elements. Creative ideas must be original, novel or different from what has been done in the past. In addition, creative ideas are relevant, meaningful or appropriate to the situation (Guilford, 1968; Runco and Charles, 1992). Combining the two terms provides a definition of creative advertising:

Creative advertising involves original messages that are meaningful to the target market and inform and persuade consumers about the sponsor organization’s ideas, products and/or services.

This definition acknowledges that it is the perception of the target audience that essentially determines both the advertising idea’s originality and appropriateness. However, as noted above, advertising must meet a commercial imperative: brand objectives must be met, and these objectives are set by the sponsor organization and are based upon their current market situation.

In this respect the appropriateness of the advertisement is determined by its ability to achieve the sponsor's objectives by communicating the brand message in a way that is meaningful to the target audience. So is creative advertising effective? The answer lies in whether a highly original and appropriate advertising idea is able to meet those brand objectives, given the advertising environment they face?

The Advertising Environment

Advertisers face an increasingly complex and complicated environment. That environment is now very different from the golden years of advertising in the 1950s and 1960s, when TV was an exciting new medium, entertainment and media options were limited, consumers were looking for new products to enhance their lives, and subsequently the motivation to process advertisements was high. As the consumer society developed, consumers became more discerning and knowledgeable, and increasingly have seen advertising, whatever the medium or format, as intrusive. Today advertisers face a multimedia environment that is highly cluttered and where most consumers have low motivation to process advertisements. Added to this is an abundance of content and entertainment options that are available to consumers at their fingertips, a general distrust of advertising, and easily accessible social sources of information. In this competitive environment, highly original and appropriate advertising offers a way to cut through the clutter and be seen and/or heard.

Ideas that are original, novel and unexpected to the target audience draw their attention and demand processing capacity (Till and Baack, 2005). However, while attention grabbing advertisements are important, this is not enough. Creative advertisements cannot be just art for art's sake, the commercial imperative of advertising means that they must communicate a brand message in a way that is meaningful and persuasive. Hence, both elements assist in determining the effectiveness of creative advertisements. Originality to grab the attention of the audience, and also appropriateness, or presentation of the core brand message in a manner that that target audience will be responsive to (Ang et al., 2014).

Nevertheless, this is not to abandon the importance of art to the process of advertising creativity. *Artistry* in advertising builds upon the core creative idea, and involves the final aesthetic qualities resulting from the executional elements that occur as part of final advertisement production. Artistic advertisements are visually attractive, flow well, and are easy on the eye. Both the difficulties in evaluating highly creative ideas, and the highly constrained environment in which advertising occurs, increase the importance of well-presented, artistic work.

The evaluation of creative ideas is a highly problematic process. Research illustrates that while evaluations of an idea's originality are relatively consistent, judgments of appropriateness are much less so, even among groups of people with similar backgrounds (West et al., 2008). Given that creative ideas involve highly unusual or novel ideas, it is difficult to get others to see how those unusual ideas make sense. In addition, high media costs mean most advertisements must get their message across in a very short period of time. Under such circumstances presentation elements matter (Csikszentmihalyi, 1999), and the need for artistry involves more than just aesthetic quality, but also ensuring that elements within the advertisement are coherent in order to reduce audience processing requirements.

In summary, creative advertising works as the originality component grabs the attention of the consumer, increasing the processing capacity they put toward the advertisement and increasing the likelihood that they take in the core brand message. Additionally, if the advertising idea is visually attractive and coherent, consumers will be more willing to attend to the advertisement and it will be easier for them to process the message. Given environment constraints these elements are particularly crucial in advertising as unlike other fields, such as for new products or the fine arts, consumers generally put very little time or effort into processing advertisements. It is therefore of little surprise that the development of highly creative advertisements is a core focus of the advertising industry.

The Creative Continuum

However, not all creative ideas are created equal. Both originality and appropriateness should be viewed as a continuum, not an absolute. While both are required for an idea to be creative, it is not easy to determine the degree to which each is needed to meet organizational objectives. In addition, increasingly advertising creativity researchers' view that these elements cannot work independently, but that effective creative advertising ideas will present appropriate brand messages in a novel way. In other words effective creative does not first grab your attention by presenting something novel, and then proceed to present the organization's core brand message, instead the novel connection is part of the brand message. The combination of originality and appropriateness presented in a coherent aesthetically pleasing way is crucial in an advertising setting, where media and environmental constraints mean advertising ideas must be transmitted in very short time periods to consumers with low motivation to process.

Hence creative advertising works to grab the attention and processing capacity of the target audience, and within that novel message, convey a brand message. Of course an alternative to achieving the same objective is to increase the frequency to exposure of less creative advertisements, but this can be very expensive. Moreover, having high repetition of uncreative advertisements can quickly lead to advertisement "wear-out" (Lehnert et al., 2013). Wear out is the situation where the effectiveness of repetitive advertisements diminishes with exposure, and may even result in negative perceptions of the advertised brand.

The Organization's Brand Objectives

What is required for a creative advertisement to be effective is dependent upon what the organization is trying to achieve. Promotional objectives range from attaining initial awareness of a new idea, to changing the perceptions consumers have toward the brand, through to final product purchase. These promotional objectives will in turn depend upon the current state of the organization's brand market position as well as product category and consumer characteristics. For example, for product categories where consumers perceive high purchase risks, such as high price or social esteem type products, less original but more appropriate advertisements may be the focus, as consumers are already highly motivated to process advertisements. In addition, the promotional objectives for existing well established brands may be more focused on appropriateness relative to originality, as the aim is on reinforcing the primary brand message to existing customers. In contrast, attention grabbing originality will be a greater focus for new brands who have to gain initial awareness of their new product and break through the clutter.

However, despite varying requirements for the two core creative components, there is little argument about the significant impact highly creative advertisements can achieve. Therefore the question becomes - why settle for a one or other of the two components? Why not just develop advertisements that are high in originality and appropriate to start with? The answer lies in the difficulties in developing highly creative advertising.

Developing Creative Advertisements

While it has long been acknowledged that highly creative advertisements can have dramatic effects, understanding how to produce them has proven more problematic. The development of creative advertisements include an array of general processes that are not unique to advertising. These general processes involve (i) problem definition, (ii) idea generation and refinement, and (iii) presentation and evaluation, albeit in an iterative and integrated fashion. However, despite the universality of these creative development processes, the advertising industry provides some unique contextual factors that influence each stage. Central to these contextual factors is the advertising agency.

Traditionally the development of large scale advertising campaigns has primarily been outsourced to advertising agencies. These advertising agencies must be equipped to develop the type of creative advertisements required by clients. This requires processes and structures that enable an understanding and management of each client's unique objectives, as well as systems to ensure effective development and evaluation of creative ideas at different stages of completion (Kover, 1970). Subsequently, agencies provide specialist creative expertise used in the generation, evaluation and production of creative advertisements, as well as the effective use of media. Central to these specialists is often a creative dyad, a copywriter and art director who work together to generate, refine, and bring to life creative advertising ideas—the "creatives."

Creative Problem Definition

Even before the creatives begin the process of generating early stage creative ideas, those processes will be influenced by how the advertising objectives have been defined. How a problem is defined influences how people go about generating a solution. In the advertising industry the sponsor, or client, will set the advertising objectives and provide information to guide the creative idea. In agencies this will often take the form of a briefing document. This document usually contains client objectives and operational requirements, brand values, and a varying degree of consumer information. This document provides cues that can prime information used in creative ideation processes, as well as acting as a basis for idea evaluation. As much of this priming information is focused on brand objectives, it is likely to increase the appropriateness of the creative ideas generated by the creatives, but can potentially limit their originality.

However, it has been identified that the extent to which problem definition information limits a person's ability to generate original solutions is dependent upon what type of solution they are trying to generate, as well as the inherent associative abilities and learnt knowledge and expertise of the people generating the creative idea. Agency creatives tend to focus on generating original solutions (Csikszentmihalyi, 1999), so if they believe through their interaction with the client, as well as their view of the creative brief, that they are able to generate more novel ideas, they are likely to do so.

In addition, while for most people extensive informational cues may result in them becoming fixated, resulting in more appropriate, but less original solutions, the strong associative abilities and expertise of creative individuals allows them to go beyond the use of these cue in their creative idea generation processes. That is not to say that a preponderance of appropriateness focused problem definition primes will have no influence on agency creative personnel. Indeed, agencies are often structured in a way that shields the creatives from too much information, at least during early stage creative ideation processes. However, the effect on the creative dyad of highly detailed appropriateness cues may be primarily due to it being seen as a signal that the client is not willing to explore more risky novel alternatives.

If creative personnel know that the client is not going to accept more novel solutions they are likely to focus on just giving the client what they want (West et al., 2008). Indeed client willingness to explore has been consistently shown to be one of the most significant influences on the type of creative advertising ideas that are generated (Koslow et al., 2006). Moreover, if the client views the agency as a vendor versus a partner, this will have a significant impact on the creativity of the advertising the agency produces.

The quality of the advertising creative is therefore dependent upon not just the idea generator's creative abilities, but the views, and relationships that are developed with those evaluating their ideas.

Creative Idea Generation and Initial Refinement

While problem definition information provides information used in idea generation processes, it is individuals who generate new creative insights. Developing creative ideas involves combination processes (Guilford, 1968; Mumford et al., 1991). Ideas that involve the combination of highly unusual domains, or areas of thought, will result in highly original combinations. However, these unusual combinations must also be seen as appropriate to those evaluating the idea. Hence advertising idea generation can be seen as involving what are referred to as divergent thinking and convergent thinking processes (Guilford, 1968) (See Divergent Thinking).

Divergent thinking involves creative leaps of insight, making connections between distant domains of thought. Convergent thinking involves connection of ideas that are more closely related (Guilford, 1968). This convergent thinking process can be used to refine early stage divergent ideas. This refinement process involves taking highly unusual or divergent connections, and undertaking further research and/or contemplative processes in order to strengthen the links between these divergent ideas. These two types of thinking can be thought of as a continuum. Within the total body of human knowledge all ideas are related if one follows a chain of connection far enough, but some concepts are more closely related than others.

The need to have expertise, and the fact that each individual's knowledge capacity is limited, means that most people specialize in certain knowledge domains. This means that external people, specialized in their own particular area of expertise, who are viewing another person's original idea, will view any connections between distant knowledge as original. However, those external observers will find it difficult to see how those ideas are connected, or make sense, as they are unlikely to possess the knowledge of the two divergent domains being connected. Developing highly original ideas that provide a novel depiction of the brand message in a manner that the target audience will see as meaningful is therefore a difficult process, requiring rare expertise.

Given that creative thinking processes involve both an ability to make unusual connections between distant domains, but also refinement of those ideas into a form that others will understand, two core types of expertise are central for advertising creatives. First is the idea generator's associative abilities. Creative individuals appear to have the ability to connect a broader range of more distant ideas than others, in what is referred to by Mednick (1962) as possessing a flatter associative hierarchy. Of course connecting distant domains of knowledge requires an individual to have knowledge of those distant domains to make those associations. Hence one would expect creative individuals to be generalists who also possess high degrees of knowledge in multiple domains, and/or a strong ability to attain such information as required. It is of course very difficult to be a generalist expert and there is an additional problem with high levels of expertise - mental set fixation (See Remote Associates).

Mental set fixation is the problem where experts have difficulties developing original connections as they become fixated on a particular domain due to their existing knowledge. One way creative personal in advertising agencies overcome this problem is by using divergent thinking techniques. These techniques are variants of the creative thinking techniques developed in multiple fields, such as the use of metaphor and analogy (Madrigal and King, 2017). These techniques are essentially associative techniques. Associative techniques force the idea generator to bring in divergent domains, or unusual ideas, to use in their connection processes. For example, the advertising creative might use a random word from a dictionary as the basis for generating new associations in relation to the core brand message. These individuals' very flat associative hierarchies means they can apply techniques that force connections between very unusual or distant domains. Such techniques would require too great a leap for most people (See Analogies).

Making distant leaps is part of the creative development process, but those leaps must also result in ideas that communicate the brand message. Advertising researchers have looked at award winning creative advertising and identified techniques that emulate what advertising creative personnel do when generating highly original and appropriate combinations. The two best known of these are the Templates Technique (Goldenberg et al., 1999) and the Remote Conveyor Model (Rossiter, 1994). Both of these approaches illustrate how great advertising creatives work to provide an unusual connection that also conveys the core brand message. The use of these techniques has been shown to improve advertising creativity, at least on student samples (Scott et al., 2004). This research points to the importance of the use of such techniques to overcome mental set fixation and help to ensure advertising that meets both the originality and appropriateness criteria. These findings are significant as it points to the fact that while the quality of creative ideas is dependent upon a degree of individual associative ability, an individual's creativity can be improved by increasing their knowledge and/or exposure to alternative domains, in conjunction with training in associative techniques.

Team Creative Processes: Expertise and Refinement

The advertising creative dyad provides additional lessons in relation to creative idea generation and refinement processes. While it is an individual who makes connections between unusual domains, he or she will be influenced in their combination process by information from their external environment. One advantage of the creative dyad is that the second creative person provides a source of additional external information. Given that in the advertising setting that other person also has strong domain knowledge and

associative abilities, the quality of this information in assisting divergent thinking processes is likely to be high. In addition, this second person not only provides a basis for divergent information primes, but also assists with initial idea evaluation and refinement processes (See Teams).

Given that it is difficult for external judges to evaluate ideas that are highly divergent connections as also appropriate, the expression of creative ideas is a risky process. Creatives acknowledge that they face constant evaluative pressure and one means to alleviate some of that pressure is having a like-minded person with which to share early stage creative ideas. During the initial creative idea generation process, the creative dyad will normally generate a number of potential advertising ideas, but present a smaller number for external evaluation outside their team. The use of a dyad allows that larger group of divergent ideas to be expressed, and refinement processes to occur, in an exchange process with a person who understands the difficulties in creative evaluation and whose strong associative abilities also mean they are likely to appreciate unusual divergent connections. This small group expression and refinement process will assist in developing stronger connections between the divergent ideas, providing arguments and refinement of those early stage ideas.

Idea Expression and Refinement

Having highly creative people generate creative advertising ideas is only one small part of the process in developing creative advertisements. Between the initial idea generation stage and final production is often a long and expensive series of interrelated and iterative steps. These steps are made complex by the difficulties in evaluating highly creative ideas and the range of stakeholders, who often have differing views on what constitutes good creative advertising. In the agency setting the primary conflict in these views is often between the creative idea generator and the final client. However, agencies have developed extensive systems and structures to assist in overcoming these conflicts and increasing the chances of developing great creative ideas, as well as having those ideas accepted (Kover, 1970).

While the creatives are largely focused on creative idea generation processes, other agency personnel will influence this process by providing information and evaluative cues. In advertising agencies, account personnel, made up of account services and account planners are often used to manage the relationship with the client as well as providing information on the market and consumers. These groups were referred to by Kover (1970) as being part of the client-centered system. Both of these groups provide valuable evaluative information, based upon both an understanding of the client and the market. An additional benefit of the use of account personnel is that it keeps a distance between the creatives and a preponderance of appropriateness criteria which may stifle their creativity. Agency production staff also influence creative idea generation processes. The media by which the advertisement makes its way to the final consumer influences the message. Given the recent rapid and ongoing changes in media, input from specialist production people with new media expertise are often provided early in the creative development process to ensure the creatives know what is feasible.

In the process of advertising development, external evaluation processes do not stop with the creative dyad and the inputs from the account and the production teams. Indeed, given the high production and media costs associated with major brand campaigns, creative advertising ideas will usually go through a series of extensive evaluation and refinement stages. In the context of the agency process the ideas the creatives select and refine will subsequently be evaluated by a creative director. The creative director is a senior creative with a boundary spanning role. They understand both the creative idea development process, but also the perspective of the client. The creative director must therefore gauge the degree of client risk tolerance, and where appropriate, work to present and persuade clients, championing the value of creative options.

After the creative director has screened and provided feedback on the creative ideas, further evaluation processes will occur involving the client and often formal testing methods. Formal testing methods provide an evaluative mechanism often in the form of copy testing but increasingly using online experimental methods (i.e. A/B testing) that can simultaneously show different versions of an advertisement to a large representative group of customers to see which version is more effective. Research suggests that formal testing may actually result in more creative advertisements, as if creatives know the testing criteria they can develop highly creative ads and then fit elements into the advertisement to meet those criteria (O'Connor et al., 2016). Hence they are not an input into ideation process, but an output criteria used in assessment of ideas. These formal tests can assist in ensuring client objectives are met, helping to sell the final creative advertising idea. Selling of creative ideas to the final client (or if the idea is developed in house to senior management) is a major focus, as ultimately it is the client who pays the bill and decides upon the final creative advertising idea to be launched.

Summary

While this entry is only able to present a brief discussion of the issues and findings evident from the literature, it is clear that there is much to be gained from research into advertising creativity. The industry provides a unique setting requiring highly creative ideas to be developed under constrained circumstance in a complex environment. This has led to the development of specialized organizations with highly refined processes. These processes assist in maximizing both the likelihood that creative ideas are initially generated, but equally important that they make it through a long and difficult process of evaluation and refinement. The industry, the ideas, the people, the processes and structures, provide a crucial area of research for developing understanding of creativity.

The Future of Advertising Creativity

As the environment changes so to do the elements within those advertisements that drive their effectiveness, and subsequently the processes required to develop them. While there is insufficient room in this chapter to discuss even a small fraction of the issues, there is one core issue that demands mention. This is the growth in new digital media. This rapid change, particularly the growth in social media, is changing consumer behaviors, reducing the prevalence of traditional media use, decreasing consumers' tolerance for advertising messages even further, and leading to organizations searching for new ways to engage with consumers.

This changing media landscape has major repercussions for how and where creative advertising campaigns are developed. In a digital social media world, the ability and propensity to develop advertisements by an organizations for the use on its own media platforms, such as webpages and social media sites, has increased dramatically. At the same time the development of high quality promotional materials has become much easier. These changes have led to a growth in organizations generating their own creative advertising content, and a reemphasis on Content Marketing. Content Marketing, involves the generation and dissemination of information that the target audience finds valuable but is not primarily focused on selling a product or service.

However, while it may be relatively easy for companies to develop high quality video and audio content, the advertising ideas themselves must still be creative. In relation to developing such creative content, it is clear that this is not a simple process. Developing great creative advertising requires a magical combination of rare associative talent and the correct environment, structures, and evaluation processes that encourage it to occur. So while the advertising environment has changed, creativity, and the ability to develop it, still rules.

Introduction

Aesthetics refers to the experience of features of our world, such as landscapes, flora and fauna, and human faces and bodies as well as human-made objects, such as artworks, music, literature, film, performance, architecture, and design products. This latter category of human-made objects has been the most studied area in the history of the psychology of aesthetics, which is the study of the psychological mechanisms and processes that underlie aesthetic experiences. This entry will briefly describe the history of the psychology of aesthetics, present the various definitions and conceptualizations of the aesthetic experience, and most pertinent to this volume, discuss the relationship between aesthetics and creativity.

The formal study of aesthetic experiences can be traced back to the work of philosophers, such as Gottfried Wilhelm Leibniz, Immanuel Kant, and Alexander Gottlieb Baumgarten. It was Baumgarten, in the early 1700s, who coined the term *aesthetics*. These scholars used introspective, conceptual, and anecdotal methods to examine and describe the aesthetic experience. In the late 1800s, psychological aesthetics branched off from philosophical aesthetics following the first formal scientific studies of the aesthetic experience, which were conducted by Gustav Theodor Fechner, a psychophysicist who studied the relationship between the physical properties of objects and people's psychological experiences of such properties.

In some of his earlier works, [Fechner \(1876\)](#) examined people's preferences for the golden section, a mathematical ratio of 1 to 1.618. Fechner's work on the golden section involved presenting to research participants a set of stimuli, such as rectangles, that varied to the extent to which they possessed the golden section property. The participants were tasked with choosing which stimuli they preferred. Fechner found that people preferred basic shapes that had the golden section property over those that did not have the property. The preference for the golden section is still widely debated today as findings since Fechner have been mixed.

As a field of study, the psychology of aesthetics after Fechner experienced consistent growth in the number of researchers entering the field, important discoveries, new methods and technologies developed for examining aesthetic experiences, academic journals, conferences, and laboratories specific to the topic (see *Relevant Websites* and *Further Reading*, below). The field of creativity experienced a similar trajectory and growth. Interestingly, aesthetics and creativity have largely been separate fields with aesthetics scholars doing mostly aesthetics research and creativity scholars doing mostly creativity research. This disconnection between the two fields becomes questionable when creativity and aesthetics are considered in practice because what people create are often later experienced aesthetically by others: artworks have their viewers, music has its listeners, architecture has its inhabitants, literature has its readers, and design objects have their users. Creativity and aesthetics represent the two endpoints of the making and experiencing continuum. One is the beginning and the other the end.

What Is an Aesthetic Experience?

Historically, scientific research on aesthetics focused on people's primarily positive responses to stimuli such as artworks, musical pieces, and design objects. The most commonly examined responses are preferences, liking, appreciation, and pleasure. This focus on positive responses may not simply be the result of the bias of researchers towards such responses, but instead may have its roots in people's common interpretation of what aesthetics means. [Jacobsen et al. \(2004\)](#) demonstrated this in a study in which they asked participants to generate words that they felt are associated with aesthetics. "Beauty" was the most common word association having been named by 91.6% of participants. Importantly, participants identified 38 different adjectives as being associated with aesthetics, and of these, 26 had positive valence. Only four words, such as "ugly" and "repulsive," were negative in valence. These

results support the idea that people see aesthetics in a positive light and may underlie the high prevalence of aesthetics research that have focused on positive responses.

Based on these and similar findings and the emphasis on positive aesthetic responses throughout the history of research on aesthetics, it is clear that aesthetics has a more positive than a negative connotation. However, what cannot be ignored is the fact that aesthetic responses are highly variable and span the entire range of negative to positive responses. Even in studies that use preference or liking or pleasantness measures, they are presented along a continuum, typically using a Likert-type or semantic differential scale in which the corresponding opposite negative responses are provided. Thus, liking is paired with disliking and pleasantness is paired with unpleasantness. More generally, positive is paired with negative.

Emotions is another category of responses that arises during aesthetic experiences. Silvia (2009) identified three types of emotions beyond the typical positive responses: knowledge emotions, hostile emotions, and self-conscious emotions. Knowledge emotions are related to the ability to understand what one is looking at. Examples of knowledge emotions are confusion and surprise both of which may be experienced when an artwork that one is looking at is overly complex and unfamiliar, and especially in the case of surprise, there are also aspects of the artwork that are unexpected. Hostile emotions such as anger and disgust may arise if the art that one is engaging with conflicts with one's belief system and goals. Hostile emotions could thus be a response to artworks that are considered offensive, insensitive, or repulsive, such as a painting depicting the horrors of war or conceptual art that purposefully defames or pokes fun at religious icons. Finally, self-conscious emotions, such as pride, guilt, and embarrassment, are related to secondary emotions, which arise during early childhood primarily because they require experience with social interactions and internalization of standards set forth by adults and society. For instance, a museum visitor looking at a sexually graphic photograph could feel embarrassed because he or she might have been taught, since a young child, that graphic nudity is inappropriate and even immoral. In this case, the content of the artwork being viewed clashes with internalized standards for appropriateness and morality.

Aesthetic experiences therefore include the gamut of responses including preference and liking and joy and satisfaction as well as anger, sadness, and anxiety. In addition, there are also very specific cognitive processes involved in aesthetic experiences. These include basic perception, or noticing and directing attention to specific elements of a stimulus, such as the shapes, objects, lines, and colors of an artwork; spatial reasoning, or making sense of the compositional structure of an artwork; imagination, or visualizing what the people depicted in an artwork might be doing as well as what might have happened before and after the depicted scene; and problem solving, or determining what artistic style a particular artwork belongs to as well as trying to comprehend what message an artist is trying to convey in an artwork. A noteworthy fact regarding aesthetic experiences of art is that the above responses occur in a very brief amount of time. Studies of people looking at artworks in museums showed that, on average, people spent approximately 30 seconds engaging with artworks that are considered masterpieces of the museums' collections. Remarkably, this duration included the amount of time spent reading the labels that accompanied the artworks (Smith and Smith, 2001). Thus, one of the distinct features of aesthetic experiences of art is the amount, complexity, and richness of responses—perceptual, cognitive, emotional, and evaluative, among others—that manifest in a relatively short amount of time.

The Aesthetics Triumvirate

The aesthetic response results from the converging effects of three components—the *aesthetics triumvirate*—that are involved in all aesthetic experiences: the object, the perceiver, and the context in which the experience is taking place. Variations within each of these components and their interactions will ultimately determine the outcome of the experience. The science of aesthetics has led to some important findings that allow predictions and explanations of some aspects of aesthetic experiences.

The Object

Visual art is the most studied category of aesthetic objects. Visual artworks have certain characteristics, both physical and conceptual, that influence how they are perceived and aesthetically experienced. One of the most basic characteristics of visual artworks is their level of abstraction, which could range from representational to purely abstract. Representational works depict people, objects, and environments such as buildings and landscapes. Examples of representational works include Leonardo da Vinci's *Mona Lisa*, Vincent van Gogh's and Rembrandt van Rijn's self-portraits, and Peter Paul Rubens' depictions of religious and mythological subjects. In contrast, purely abstract works have no recognizable objects or figures and instead may be comprised of splotches of color, basic shapes, and lines. Examples of abstract works include Jackson Pollock's drip paintings and Kazimir Malevich's black square, which as the title suggests, is a canvas painted in pure black.

In general, people show a preference for representational artworks over abstract artworks. This effect appears to be related to the ease of which people are able to make meaning of representational artworks (Millis, 2001), a process that is initiated by the simple recognition of what is depicted in the work, which then allows one to interpret and understand what one sees and perhaps to relate personally to the work. In contrast, abstract artworks not only have little to no recognizable objects, but they often also require the viewer to determine and interpret the concepts and ideas behind the works, which require background information that some art viewers might not have. This lack of information makes the search for meaning difficult, if not impossible, leaving the viewer unable to cognitively engage with the artworks.

In addition to level of abstraction, there are also visual and structural characteristics of artworks that influence the manner in which they are perceived and aesthetically experienced. Artists devote considerable energy to composing the various elements of their creations so that the visual impact and expressive quality of their artworks are maximized. One important aspect of composition is visual balance. For a painting, balance is achieved when the individual elements of the painting are balanced around the center of the canvas. It is important to note that the “center” does not have to be the geometric center of the pictorial frame, but instead could be at any location in which the weights of individual elements are balanced ([Arnheim, 1982](#)). For example, the weight of a large, visually “heavy” object near the edge of a painting may be counteracted by several smaller objects on the other side of the painting.

Artists go to great lengths to create works that are optimally balanced. An artist known for his systematic and rigorous compositions is the Dutch artist Piet Mondrian, who is famous for his abstract paintings from the 1920s and 1930s that were made up of black horizontal and vertical lines and colored squares and rectangles (primarily in blue, red, and yellow), of various sizes and that were carefully arranged on a white background. Mondrian spent a great deal of time and energy working and reworking his paintings so that each would have the best possible composition. A question that arises is whether viewers of artworks, such as those by Mondrian, are actually able to determine whether one artwork has better compositional balance than another. [McManus et al. \(1993\)](#) addressed this question in a study that asked participants for their preference for one of two versions of a pair of Mondrian paintings. One version consisted of an image of an original Mondrian painting while the other version consisted of the same image that had some of its elements modified so that its composition was perturbed. The results of the study showed that participants preferred the original over the perturbed versions significantly above chance level, which is evidence that people are able to perceive differences in, and variations in the quality of, the compositions of artworks. According to [Locher \(2003\)](#), “the structural skeleton or network created by a skilled artist is the correct or best organization of its pictorial features ... Such an organization should be, according to this view, highly salient to an observer regardless of his or her level of sophistication in the visual arts” (p. 159). Locher’s *visual rightness theory* provides evidence for the relationship between creativity and aesthetics such that what the artist wishes to express in a work is able to be aesthetically experienced by the person viewing the work.

The Person

The second component of the aesthetics triumvirate is the viewer, who stands at the receptive end of the process that began with the artist creating an artwork. There are certain characteristics of the viewer that could impact how the aesthetic encounter transpires. The most researched of these characteristics is arguably the amount of knowledge the viewer has about art. Such knowledge could come from formal education in art, such as taking art studio, art history, or art theory classes, or informal experiences with art, such as having art as a hobby, regularly visiting art galleries and museums, and attending art shows, performances, and similar events. Research showed specific differences in aesthetic experiences between people who were knowledgeable and less knowledgeable about art. For example, art novices are more likely to think about artworks in terms of the content that they depict and how the artwork might relate to them personally ([Hekkert and van Wieringen, 1996](#)). In contrast, art experts think about artworks in terms of the art style that they belong to (e.g., Renaissance, Abstract Expressionist, and Impressionist) as well as their formal characteristics, such as their compositional structure ([Cupchik and Gebots, 1988](#)).

Differences between these two groups are also reflected in how they engage with representational and abstract art. Because of their ability to process art in terms of style and formal elements, art experts are more interested and are better able to appreciate even the most abstract and conceptual artworks. Art novices, however, have difficulty engaging with, and show little appreciation for, such works unless they are provided with information that could help them to interpret the works. For instance, an art novice looking at abstract paintings by Willem de Kooning might not know how to interpret the work. The late career paintings that De Kooning made consisted of thick, curving, ribbon-like lines that flowed across swaths of color with no discernible objects on the canvases. This viewer could benefit from some information about the paintings and about the artist. de Kooning made the paintings near the end of his life when he was struggling with serious health issues and they were a significant departure from his earlier works, which were harsher in character and which often included figurative elements. This additional information gives the artwork more meaning.

The Context

The specific characteristics of the viewer and of the artwork determine, to a large degree, how the interaction between the two will transpire and what will be the outcome of the aesthetic experience. The third component of the aesthetics triumvirate is the context in which the aesthetic experience takes place, or in other words, where the interaction between the viewer and the artwork occurs. Although context is as influential for the aesthetic experience as the two other components, it is the one that is least understood. This state-of-affairs stems from the lack of research on the effects of context, which in turn is likely due to the methodological difficulties associated with isolating the effects of context on the aesthetic experience. However, in the past decade or so, we have learned a great deal about the specific effects of context.

For instance, specific features of the physical space in which an artwork is presented affect how that artwork will be experienced. The traditional context for art is undoubtedly the art gallery or museum. However, in recent years, the massive expansion of digital media use, especially for presenting and viewing art, has led to questions such as what are the advantages of viewing a genuine artwork in a museum versus a printed reproduction or digital version of the same work presented on a computer screen or through

some other format? Studies have shown that aesthetic experiences with genuine artwork presented in the museum are generally more intense than aesthetic experiences with the same artwork presented in a different format. Viewers also find artworks presented in a museum to be more likeable and interesting than the same artworks presented in a laboratory (Brieber et al., 2014).

The context therefore serves as the basis for the interaction between the artwork and the viewer, and it is this interaction that represents the relationship between creativity and aesthetics. In this sense, the creative work of the artist is encapsulated in the artwork, and the person engaging with this work will examine, attempt to make meaning of, and evaluate the work. The next section formally describes the relationship between creativity and aesthetics.

Models of the Aesthetic Experience: From Creativity to Aesthetics

The two earliest and currently most highly cited models of aesthetic experiences were proposed by Chatterjee (2004) and Leder et al. (2004). Both models describe the main processes that take place during aesthetic experiences in terms of three broad information processing stages. In the first stage, the viewer automatically processes the basic visual features of an artwork, such as its complexity, symmetry, contour, and color. During the second stage, the viewer uses his or her memory to identify and think about what is depicted in the artwork and the art style to which the artwork belongs. Finally, in the third stage, the viewer attempts to derive meaning from the work and determine the concepts and ideas underlying its creation. It is also at this final stage where judgments about the artwork are made.

In his Mirror Model of Art, (Tinio, 2013) argued that these three broad stages of the aesthetic experience of art correspond directly to the three stages of art making, although in a mirror-reversed fashion. Specifically, art making begins with a concept or idea that the artist initially expresses—using painting as an example—as a rough sketch on paper or underdrawing on canvas. Subsequently, the artist develops on this initial layer by elaborating on the drawing or by adding more materials, such as paint, on the canvas. It is at this second stage that the content of the work such as objects and forms become visually distinct. Lastly, the artist finalizes the work by further refining the content and adding color and other finishing touches. According to the Mirror Model, this last stage of the creative art making process is where the aesthetic experience begins with the viewer quickly and automatically processing the surface-level features of the artwork. The viewer then engages with the content of the work, identifying objects that might be recognizable and categorizing the artwork in terms of its style. Finally, the viewer attempts to make meaning out of the work and tries to understand the ideas and concepts underlying its creation as well as what the artist might have been trying to express. Therefore, the three stages of the aesthetic experience correspond, in reverse order, to the three stages of the creative art making process.

The Mirror Model of Art describes the interface between art making and art viewing. This formal description represents aesthetic experiences in general in that creative products have their audience: paintings and sculptures are viewed and evaluated; poems and stories are read and contemplated; architecture and design products are used and appreciated; and music is listened to and enjoyed. In these examples, creativity and aesthetics are closely intertwined. It is therefore curious that creativity and aesthetics, as scientific fields, have remained largely separate with scholars from each side rarely integrating with the other. Creativity and aesthetics scholars have started to address this state of affairs (Vartanian, 2014). Both fields can only benefit from the work that they do to integrate the two sides.

Conclusion

Over a century's worth of scholarship on the psychology of aesthetics has revealed the complex nature of the aesthetic experience. The aesthetic experience involves cognitive responses such as perception, memory-related processes and meaning-making; a wide range of emotions, both typical such as pleasure and displeasure and liking and disliking, and atypical, such as repulsion, disgust, and shame. The above responses are a product of an interaction amongst the aesthetic object, the perceiver, and the context in which the aesthetic experience takes place. Finally, creativity and aesthetics are related in such a way that stages of the aesthetic experience correspond to stages of the creative process.

Introduction

The relationship between creativity and alcohol is complex and far from fully understood. There is a myth surrounding the use of alcohol that is sustained by the dramatic acting out of individuals under the influence and the high number of creative individuals who have been publicly identified with abuse and addiction problems. The fuzzy notion that somehow alcohol improves creativity is based on the romantic misconception that these substances release inhibition allowing insights and creative achievement to flow. Very little objective research or self-reports from creative individuals support this idea.

In order to understand whether alcohol abuse is higher than average in creative people a baseline needs to be established. The World Health Organization estimated that in 2018 3.3 million deaths were alcohol related. This represent 7.6% of men who died and 4% among women.

Alcoholism is defined as repeated intake of alcoholic beverages to an extent that causes repeated or continued harm to the drinker.

Consequences of heavy drinking can include acute health problems, traffic injuries and deaths, accidental injury including alcohol poisoning, suicide, high risk sexual behavior, and violent crime. Specific health problems include cirrhosis of the liver, mouth cancer, pancreatitis, epilepsy, TB, colorectal cancer, hypertensive heart disease and breast cancer. There are also serious social and economic ramifications related to alcohol abuse.

Globally alcohol consumption continues to increase – 38.3% of the world population consumes alcohol but there are wide variances based on local cultures, socioeconomic factors and availability. Many Muslim countries, where there are primarily abstainers, have a very low percentage of alcohol dependence while other countries have very high levels of alcohol consumption, especially among men. Highest percentage consumption rates per capita are in countries in Eastern Europe including Belarus, Moldova, Lithuania, Russia and the Ukraine although consumption showed a significant decline from 2004 to 2018. One problematic trend worldwide is increased consumption per individual drinker.

This entry reviews the physical effects of alcohol as well as its influence on creativity. Research regarding the unusually high level of alcoholism in creative professions will be presented along with a discussion of the reasons. Finally the depiction of alcohol in the arts will be discussed.

Effects of Use

Physical Effects

Small doses of alcohol may help stimulate some aspects of brain function but alcohol is otherwise a depressant. *Encyclopedia Britannica* (2019) online stated that as more alcohol is consumed, an individual becomes more depressed, going on to sedation, stupor, and coma. The excitement phase exhibits the well-known signs of exhilaration, loss of socially expected restraints, loquaciousness, unexpected changes of mood, and occasionally uncontrolled emotional displays. This may result from an indirect effect of alcohol in suppressing the function of inhibitory brain centers rather than a direct stimulation of the manifest behavior.

[☆] *Change History:* July 2019. Steven Pritzker updated the text throughout.

This entry is a revision of the first edition article Alcohol, Substance Abuse and Drugs by Steven R Pritzker, volume 1, pp. 53–59, 1999, Elsevier Inc and Substance Abuse and Creativity in the second edition, volume 1, pp. 390–95.

Prolonged use of alcohol damages the health of many alcoholics. Consuming four drinks a day or more can cause high blood pressure, coronary heart disease and failure, and stroke. Prolonged alcohol use is also associated with brain damage and the development of neuropsychological disorders. Impairments may include deficits in short-term memory, disrupted cognitive and motor functioning, poor attention span, difficulties with problem-solving and learning new information, sexual dysfunction, and suppression of the immune system.

The lack of inhibition caused by drinking is directly linked to criminal behaviors, including physical violence and homicide. Legal problems as well as divorce also increase. Alcoholism can cause death from cirrhosis of the liver and impaired motor ability relating in alcohol related fatalities in automobile accidents, falls, and drowning. High levels of alcohol are found in 36% of suicides.

Effects of Use on Creativity

Some eminent creative people believed alcohol was a vital component in their success. The most common use was to overcome fear and anxiety. Aristophanes, in a play written in 424 BC, wryly commented on the benefits of alcohol: "When men drink, then they are rich and successful and win lawsuits and are happy and help their friends. Quickly, bring me a beaker of wine, so that I may wet my mind and say something clever." Dorothy Parker said, "Three highballs, and I think I'm Saint Francis of Assisi."

Other creative people drank to escape the difficulties of life. The sensitivity and awareness which made their work special also made them more prone to depression and a sense of isolation. In many cases, alcohol was used as a type of medication to dull the sharp edges of life. Tennessee Williams seemed to be speaking about his own depression and addiction when he had one of his characters in *Cat on a Hot Tin Roof* say, "Mendacity is a system that we live in. Liquor is one way out an' death's the other."

In some cases, creative professions may be the only work an alcoholic could do. The individual has the freedom to drink and work as a writer or painter. Maurice Utrillo, who struggled with alcoholism and depression, could not keep an ordinary job. He was encouraged to paint by his mother as a diversion from his alcoholism (Harris, 2005).

A sense that alcohol somehow contributed to their creativity (perhaps used as a justification for their drinking) helped demolish the long-term productivity or shortened the lives of many eminent creative people. Younger creative people still have the physical resilience to drink heavily and get their work done, but as they age it becomes more difficult, which is not surprising considering the physical effects of alcohol.

Of course, alcohol can deter productivity even when it is not used while an individual is working. Rothenberg defined three states of drinking for the writers he studied:

1. Early in their career, they only drink after work.
2. Drinking begins to occur during the day as the need for alcohol increases, which is the progression experienced by most alcoholics. In the case of writers, the loneliness of the job combined with the anxiety and uncertainty of the work can lead to a state of 'irritability.' Alcohol is used as a sedative which helps soothe frayed nerves.
3. The increased drinking results in a deterioration in the quality of the work.

Rothenberg cautioned that each case is individual and may be triggered by elements unconnected to writing such as genetics or family history. When the parent whom the writer lovingly and competitively identifies with is an alcoholic, then the dangers of alcoholism are particularly high. Examples include John Cheever and William Faulkner. F. Scott Fitzgerald summed up the danger of drinking in his work and life: "First I take a drink. Then the drink takes a drink. Then the drink takes me."

Experimental Research

Results of research using non-eminent participants indicated that drinking alcohol may exaggerate an individual's self-assessment of his or her work. One study found that as Aristophanes suggested, low doses of alcohol did not affect the quality of creative work, but participants who believed they drank alcohol *thought* their work was better. In another study, participants who thought they drank alcohol produced more creative combinations of wildflowers even if they had a placebo. This suggests that just thinking one has consumed alcohol may loosen some people's inhibitions.

A few researchers attempted to determine if alcohol facilitates creative writing under laboratory conditions. There are indications that alcohol significantly increases the number of words produced, confirming anecdotal accounts of writers who found alcohol an aid in producing work, but quantity does not necessarily equal quality (Gustafson and Norlander, 1995).

An experiment indicated some short-term benefits from alcohol consumption measured at 0.075 including improved creative problem solving abilities and better performance on the Remote Associates Test. (See Remote Associates) If alcohol does contribute to helping solve creative problems, at least on a short term basis, it would offer some explanation for its use by creative individuals (Jarosz et al., 2012) Another study measured the effect of alcohol on a placebo group, and an alcohol group during different phases of creativity with a lower alcohol rate of 0.03. The researchers concluded that the mildly intoxicated participants had less executive control but improved their creative problem solving ability compared to the placebo group. Divergent thinking ability was not influenced by the alcohol (Benedek et al., 2017).

Ludwig (1990) concluded 9% of his sample had helped their creativity by using alcohol; however, he cautioned that the perception alcohol helps creative work could be exaggerated by the properties of alcohol. He pointed to John Cheever, Eugene O'Neill, and Jackson Pollock as examples of creative people who gave up alcohol. However, no studies have examined how alcohol affects accomplished creative individuals under actual working conditions.

Extent of Use of Alcohol Among Eminent Creative People

Alcohol and creativity have been linked by the fact that many eminent creators have been alcoholics. [Table 1](#) is a partial list which is impressive because there are numerous eminent writers, artists, performers, and musicians.

The largest scale attempt to identify the level of alcoholism in eminent creative people was done by Arnold Ludwig, who in 1995 reviewed the lives of 1004 eminent people who had a biography reviewed in *The New York Times Book Review* between 1960 and 1990. He assessed alcohol dependence or abuse on the basis of physical problems, work interruption or poor performance, personal and interpersonal problems, and arrests. He found: "Among eminent people, 26% experience alcohol related problems during their lifetime, 23% of women and 27% of men." Creators in the arts were much more at risk: "Actors or directors, musical entertainers, sports figures, fiction writers, artists and poets (29% to 60%) have higher rates of alcohol dependence or abuse than natural scientists, soldiers, social scientists, social activists and social figures (3% to 10%)." (1995: 133–134).

These results are considerably higher than the 7.7% rate of combined alcohol abuse and dependence of alcoholics in the United States. Men greatly outnumber women and in contrast to eminent creators, rates of alcoholism declined with age rather than increased. Higher rates of alcoholism among creative artists, especially writers, were found in a number of other studies. One study found that 30% of the Iowa workshop for creative writers had a problem with alcoholism at some point in their lives. Another study found that female writers had an alcoholism rate of 20% relative to a control group rate of 5% (See Writing and Creativity).

[Rothenberg \(1990\)](#), who worked as a psychotherapist with some eminent writers, pointed out that higher rates of alcoholism in the creative arts could be encouraged by the nature of the work, which is often isolating and allows the individual writer or artist to drink more easily. Alcoholism is found less frequently in scientific professions where personal vision is less important than producing objective data that can be replicated.

Cultural conditioning plays a role in the entertainment business where alcohol abuse is a serious problem. High profile actors with acknowledged alcohol abuse issues include Mel Gibson, Bradley Cooper, Ben Affleck, and Drew Barrymore. The list of musicians includes Eric Clapton, Pete Townshend, Eminem, Billy Joel, Keith Richards and Ringo Starr. Some of these celebrities are now sober.

Amy Winehouse wrote a song called Rehab and inevitably there is a group with that name. Unfortunately many people such as Winehouse died before they got to rehab, or rehab did not work, and the list of early deaths of highly talented individuals is a long one.

Families of Alcoholic Creative People

Ludwig found 12.2% of the fathers and 2.4% of the mothers of eminent creative artists were alcoholic compared to 6.6% of the fathers and 0.5% of the mothers in other professions. Furthermore, 10.6% in the creative arts had alcoholic siblings compared to 6.3% of others. Other studies found that 11% of the writers had at least one alcoholic parent compared to 7% of the total sample. Examples of eminent creative people who came from alcoholic families include Charlie Chaplin, Tennessee Williams, Orson Welles, and Truman Capote.

The coincidence of alcoholism and other addictions in families is confirmed by genetic research. Sarah Hartz and Laura Bierer stated:

Robust genetic associations have been found for alcohol dependence, nicotine dependence, and cocaine dependence. (2010: 107)

As genetic research becomes more sophisticated, advanced techniques may eventually reveal if there is a genetic link between alcohol abuse and specific creative talents.

There is a paucity of research looking at alcoholism in families. In a study on painters, the only characteristic which differentiated excessive drinkers from moderate drinkers was having the same profession as their father. In one case, the son of a successful father exhibited anxiety over competition with the father. In another case, the son pursued painting to satisfy his father's unfulfilled ambition "at the cost of inner development and constant strain."

Alcoholism in the Arts

Alcoholism inevitably creates self-destruction and conflict which provides material for creative work. The fact that so many influential creative people were alcoholics led to prolific inclusion in songs, books, plays and films:

- Alcohol abuse is the theme in films such as *Lost Weekend*, *Barfly*, *Leaving Las Vegas*, *The Days of Wines and Roses*, *The Verdict* and hundreds of others. Alcohol and drug use are frequently depicted favorably in films; a review of movies released in 2016 showed 28 out of 33 movies had scenes where alcohol or drugs was consumed.
- Shakespeare addressed the perverse influence of alcohol in many of his plays. Award winning plays where alcoholism is a key element include *Long Day's Journey into Night*, and *Who's Afraid of Virginia Woolf*.
- Alcoholism is represented in novels such as *Under the Volcano* and *Postcards from The Edge*, memoirs from musicians, movies stars and everyday alcoholics, and biographies of alcoholic figures such as Ulysses Grant and Spencer Tracy.

- Websites list hundreds of songs about alcohol in a variety of genres such as Beyoncé's *Drunk in Love*, Merrill Haggards *I Think I'll Just Sit Here and Drink* and *What Good Can Drinkin' Do* by Janis Joplin. A study of Billboard Magazine's biggest hits from 2005–07 identified 169 (21.3%) out of 793 songs that referred to alcohol. A review of YouTube pop videos in the UK indicated a prevalence of alcohol inspired lyrics and situations with an emphasis on the positive aspects of drinking. Research indicated the glamorization encourages adolescents to drink more so they can emulate their idols.

Also inherently dramatic is "Recovery" from alcoholism and drugs with its triumphant elements. It has been the subject of many books including Alcoholics Anonymous literature, memoirs of celebrities such as Elton John and self-help books by the score. Some recovery movies include *28 Days*, *My Name is Bill W.*, and *When a Man Loves a Woman*. Songs include two called *Sober* by Pink and Kelly Clarkson.

All this self-reflective activity by creative individuals suggests that using creative self-expression could be valuable in healing. There are recovery programs that are using expressive arts in a variety of ways to heal and transform individuals using art, writing, dance and music. Natalie Rogers (1993) suggested that expressive arts could help an addict achieve an altered state of consciousness replacing the need for mind-altering drugs (See Expressive Arts).

Summary and Conclusions

Reasons why the use of alcohol is more prevalent in creative professions include:

1. **Genetic predisposition:** A higher percentage of fathers, mothers, and siblings of eminent creative people were alcoholics.
2. **Self-medication:** More people have affective mental illness so they may be self-medicating with alcohol and other drugs.
3. **Opportunity:** Writers, artists, and composers often work alone so they can drink or use drugs more often without anybody knowing about it.
4. **Subculture:** Performers live in a subculture where alcohol and drugs are easily available and are a part of the culture. Previous stars who died dramatically and publicly from use of alcohol and drugs may be idolized and emulated by the next generation. In the case of musicians and actors, there may also be an element of trying to be a part of the culture of their younger audience as they found themselves aging.
5. **The Difficulty of the Work:** Creative work is tough and uncertain, and the road to success for most aspiring creators is paved with disappointment, self-doubt and rejection. Creative artists suffer blocks at times. Alcohol may provide temporary release from the self-doubt and pain.
6. **Stress:** Success brings its own pressure. Creators often feel they must match or exceed their previous work. Simonton (1994) proposed alcohol use may provide the user with a self-handicap, a convenient excuse that justifies failure. For performers such as musicians, comedians, and actors, the pressure of having to be at the top of your game because the stakes are so high can encourage some creative people, especially live entertainers, to use alcohol to overcome their performance anxieties, loosen their inhibitions and to wind down so they can sleep after being energized by their performances (Ludwig, 1995: 136–137)
7. **As an Aid:** Some creative people stated they felt alcohol helped their work, especially in overcoming anxiety during the initial stages of creation.
8. **Widening Consciousness:** The idea, reinforced by some creative individuals, that they use alcohol in an attempt to widen their consciousness and seek new perspectives.

Stephen King in his book *On Writing* wrote frankly about drug and alcohol problems: "The idea that creative endeavor and substances are entwined is one of the great pop-intellectual myths of our times." (in Hyde and Zanetti, 2002: 210). He acknowledged that, "Creative people do probably run a risk of alcoholism and addiction more than those in some other jobs, but so what? We all look pretty much the same when we're puking in the gutter."

The number of variables involved leave the relationship between creativity and alcohol with many unanswered questions. Far more work needs to be done to understand the physiological effects of using alcohol in relation to creative activity as well as the psychological dynamic. Innovative methods are needed to research this challenging field.

Altered States of Consciousness An “altered” conscious state can be defined as a pattern of phenomenological properties recognizable by an individual (or group), or by an external observer of that individual (or group), as demonstrating a major difference in behavior and experience from an ordinary baseline pattern of wakefulness. An “altered state” involves changes in a number of “subsystems” of consciousness such as perceptions, cognitions, emotions, and sense of time and space. Both dreaming and non-dreaming sleep differ from baseline consciousness, thus qualifying as “altered states.” Others include variants in wakefulness resulting from meditation, prayer, hypnosis, “peak experiences,” “mediumistic” and “channeling” rituals, and more. Studying the phenomenology (or subjective experience) of an “altered state” can be accomplished through observation, self-reports, interviews, brain scans and other psychophysiological measures, or the administration of psychological tests and inventories

Consciousness The term “consciousness” derives from the Latin *conscire*, to know with, or to be cognizant of something. Ordinary waking consciousness reflects the explicit knowledge of one’s situation and one’s sense of personal existence. In general, “consciousness” can be described as a phenomenological pattern that characterizes humans or other sentient organisms at any given time and place

Creative The term “creative” can be applied to any act, idea, or product that changes or transforms an existing domain of human endeavor. A phenomenon is creative if it is novel and, in some manner, useful or appropriate for the situation in which it occurs

Phenomenology This is an approach to disciplined inquiry that emphasizes the nature of conscious experiences in their own terms. Phenomenologists investigate the relationship between conscious behaviors and the objects of such acts, thereby differing it from introspection

Transitional States of Consciousness Typically, a “transitional conscious state” lasts for a brief time period, mediating between two longer lasting patterns of consciousness. Hypnagogic states are transitional, because they mark the shift from a baseline state (wakefulness) to a long-lasting altered state (sleep). Other transitional states include daydreaming, reverie, napping, and hypnagogic or hypnopompic states, the former occurring when falling asleep and the latter upon waking from sleep. Transitional states are sometimes called “transliminal,” because they cross a “limen” or threshold

Historical Overview

The terms by which people make sense of their world are social artifacts, products of historically situated interchanges among people. In the history of Western civilization, not all individuals have had equal opportunities for creative expression. For example, until recently the creativity of women was rarely valued or encouraged in Western cultures; women were given few occasions to develop the skills (e.g., critical thinking) or life circumstances (e.g., solitude) on which creative work often depends. One of creativity's "Four Ps" is Place, the historical and cultural context of Person, Process, and Product.

Shamans are community-sanctioned practitioners who purport to access information in what Westerners would call "altered states." Shamans then use this information in service of their community. For example, Pablo Amaringo, a Peruvian shaman, interacted with "spirits" after drinking ayahuasca, a mind-altering brew made from Amazonian plants. His paintings of the "spirit world" attracted the attention of tourists. Using funds from the sale of his paintings, Amaringo established an art school for young people from the Amazonian rainforest. Jeremy Narby, an anthropologist, took three scientists to the Amazon to imbibe ayahuasca under the guidance of shamans. All three reported creative insights that helped them solve problems relating to their work (Narby and Huxley, 2009).

The paintings in the Lascaux Caves of southern France date back at least 17,000 years; the prone figure depicted in the cave is often regarded as a shaman experiencing changed consciousness, perhaps dreaming. Cave art often depicts substances now referred to as "psychedelic" (from the Greek words *psyche* and *deloun*, i.e., "mind-manifesting"). Such substances as the peyote cactus apparently helped many shamans enter the "spirit world." Psychedelics provided a technology that triggered theatrical performances, mythic narratives, chants, songs, dances, and other products currently labeled "creative." Traditional Siberian shamans still "journey" to the "spirit world" with the aid of psychedelic mushrooms, ritualistic dancing, and/or rhythmic drumming.

Initiates of the Eleusinian Mysteries in ancient Greece probably used a potion containing a psychedelic fungus to fathom what the poet Pindar called "the end of life and its god-sent beginning." India's Vedic hymns sing the praises of *soma*, an intoxicant, perhaps a psychedelic mushroom, that was "all pervading, swift as thought."

In pre-Conquest Mesoamerica, people used their talents creatively in the service of their religious beliefs. Aztec poets and musicians rhapsodized about the "dream flowers" that took them to another world. Wasson found similarities between the employment of psychedelics in pre-Conquest Mexico and their use in ancient Greece; mind-altering plants adorn both the vases of Attica and the architecture of Mitla.

Cross-Cultural Comparisons

Societies have an assortment of terms to describe activities resembling what Western psychologists refer to as creativity; for example, the first hexagram of the Chinese "Book of Changes" (or *I Jing*) is *Ch'ien*, the "Creative Principle." Most Asian, African, and Native American traditions also have used creative imagination to enrich and enhance everyday life. Novel and original contributions were typically seen as gifts from deities or spirits who used humans as "channels."

When the Catholic Church's power was dominant, Western cultures tended to consider "channeling" wicked and demonic. Following the Renaissance, science and medicine prevailed. However, the rituals of "mediums" and "channelers" were now cast in psychopathological terms, even though their phenomenology was quite different. In contrast, traditional Eastern worshippers, such as Buddhists, Hindus, and Taoists, had intricate vocabularies to describe the phenomenology of changed consciousness.

In dreams and in waking visions, the Maya people asked their deities to appear before them, reflecting a tradition of visionary ecstasy. Mayan artists depicted an overlap between the world of everyday reality and the "spirit world," suggesting that their phenomenology was more "dreamlike" than that of their European conquerors. Freud described the conscious "ego" as the external boundary of a volatile reservoir of both conscious and unconscious "psychic energies." This resembles the shamanic energetic model of the human body embedded in a community and environmental matrix. However, from the shaman's perspective, the "unconscious energies" of the Freudians were not blind and irrational, but keenly intelligent forces originating in the earth itself.

Creativity and Psychedelics

Psychedelic substances and other drugs affect consciousness by modifying the process of synaptic transmission in the brain. Excitatory and inhibitory connections are carried out by transfer of biochemicals (by neurotransmitters) across the synaptic gap between neurons. Drugs can affect synaptic transmission in a variety of ways, such as blocking the production or reception of a neurotransmitter or mocking a neurotransmitter, thus effectively increasing its activity level. The phenomenological pattern that a drug evokes depends upon which neurotransmitters it affects. In the case of psychedelics, the outcome seems to be a disruption of logical analysis and the automatic reality-checking functions of the brain, probably connected to the ability of these drugs to block serotonin transmission. In psychotherapy, psychedelics can produce a depatterning influence that breaks up the individual's habitual experiences of the world, tending to increase the individual's suggestibility and susceptibility to reprogramming (Baruss, 2003).

Several creative individuals have produced anecdotal accounts claiming that their phenomenology has been affected by ingestion of psychedelics (Krippner, 2017). They include neurologist S. Weir Mitchell, British writer Aldous Huxley, U.S. naval technician John Busby, actors Cary Grant and Rita Moreno, and the Canadian architect Kyo Izumi. Both Kary Mullis and Francis Crick attributed their Nobel Prize-winning discoveries (i.e., a DNA detection method; the double helix structure of DNA), at least in part, to experiences with LSD.

The “Model Psychosis” Assumption

Some early researchers reported that LSD users gave highly imaginative, although bizarre, responses to Rorschach inkblots and other measures. In summarizing his observations of LSD users in 1976, the psychoanalyst Silvano Arieti found that the use of “primary process mechanisms” was enhanced, but that the “secondary processing” required to put the imagery to creative use was impaired. These studies and related research, conducted with artists and non-artists, and with laboratory participants and “street users,” identified many dysfunctional results of informal psychedelic drug use. However, no conclusive data supported the notion that psychedelics could produce a “model psychosis.” In 1988, T. E. Oxman and colleagues reported a content analysis of 66 autobiographical accounts of schizophrenia, psychedelic drug experience, and mystical experience, as well as personal experiences in ordinary consciousness. They concluded that there is a “clear dissimilarity” among changed states of consciousness, especially between psychosis and psychedelic drug states, as a refutation of the “model psychosis” perspective. Creativity, of course, is only one of many behaviors affected by psychedelics. One of creativity’s “Four Ps” is Process, and psychedelics may accelerate the incubation phase.

Psychedelic Research With Volunteers

Another of creativity’s “Four Ps” is Person, and several studies have been conducted with volunteers to determine the relationship between psychedelics and creative behavior. For example, to study the effects of LSD on creativity test scores, a test battery (also administered to a control group) was given before LSD ingestion, and alternative forms of the same tests were administered 2 h later. The researchers observed that changed scores on the creativity tests favored the LSD group, even though they did poorly on tests requiring visual attention. In another study, one-third of the participants were administered a high dose of LSD, one-third a low dose, and one-third an amphetamine. Questionnaires were administered to each group prior to drug ingestion and again at two follow-ups. The low LSD and amphetamine groups obtained similar results, but the high LSD group bought more musical records, spent more time in museums, and attended more musical events. Another study dispensed psilocybin to volunteers who had completed tests for creativity and for brain damage; they were re-tested after drug ingestion. A significant inverse relationship between the scores on the two tests was reported.

A 2018 study found that both convergent and divergent thinking test scores improved following frequent “microdoses” of LSD. In summation, psychedelic substances affect several subsystems of consciousness that enhance creativity (Pappas, 2018). However, these insights need to be implemented in the elaboration phase of creativity.

Psychedelic Research With Selected Participants

In the 1960s, LSD was administered to 50 well-known artists at the Max Planck Institute in Munich. The artists concurred that the experience was of value, and the ensuing work was displayed in a Frankfurt gallery. In a study on the effects of mescaline and LSD on four U.S. graphic artists, a panel of art critics judged the paintings to have greater aesthetic value than the artists’ usual work, noting that the lines were bolder and the use of color more vivid. A similar study giving LSD to American artists resulted in judgments by a professor of art history that the LSD paintings were more imaginative, especially in color, line, and texture, although the technique was poorer.

A study of professional workers in creativity-related fields showed that mescaline ingestion resulted in a statistically significant increase in creativity test scores, with enhanced fluency of ideas, visualization, and field independence. Interview and questionnaire data revealed that half the group had accomplished a great deal more during the mescaline session than would have characterized their ordinary workday. All participants reported positive reactions to mescaline, but many were unable to focus because they were diverted by the experience itself.

In one study, ayahuasca was ingested by 24 volunteers. Their pre-session and post-session scores on creativity tests revealed a decrease in convergent thinking and an increase in divergent thinking. The researchers concluded that ayahuasca “enhances creative divergent thinking,” but that “additional research ... is warranted” (Kuypers et al., 2016, p. 3407).

Cross-Cultural Considerations

The potent red mescal bean, *Sophora secundiflora*, has been found with the remains of the extinct bison and the tools and weapons of early North American hunters. Anthropologists have noted that the chants and poems used in contemporary spiritual ceremonies make great demands on the practitioner; the Yakut shaman in Siberia, for example, has a poetic vocabulary of some 12,000 words used in *Amanita muscaria* mushroom rites, as compared to 4000 in ordinary daily endeavors. The Zuni rain priests of New Mexico have a special language with which they converse with “spirit birds” once they have ingested *Datura meteloides*. For native people, these substances are not taken trivially, for momentary pleasures or “cheap thrills” (De Rios, 2003). To maintain their standards, native groups require a precise amount of time for the preparation of psychedelic concoctions, and the mixture of ingredients must be exact. Even then, there may be an initial period of bodily discomfort, physical pain, or vomiting, followed by encounters with “malevolent spirits.”

Psychedelics often foster creative behavior among indigenous people by reinforcing cultural myths and traditions. The ayahuasca-ingesting Siona shamans of the Amazon have provided phenomenological reports that involve categorizing the induced visions into

culturally meaningful symbols and experiences. On the other hand, psychedelics often stimulate creativity among specialists in industrialized societies by *deconditioning* them to their cultural traditions; their images are likely to tap into their personal rather than their social *imaginario*.

Creativity, Hypnagogia, and Hypnopompia

Colorful images often occur during hypnagogic (from the Greek *Hypnos*, or sleep, and *agogeus*, or leading into) reverie, the transitional state occurring during the onset of sleep. There is a similar association between creativity and hypnopompic (from the Greek *Hypnos*, or sleep, and *pompe*, or leading out of) reverie, which occurs as one awakens from sleep. These transitional states, referred to as hypnagogia and hypnopompia, resemble dreams in that both contain visual, auditory, and/or kinesthetic imagery. However, material from these twilight states is not typically characterized by narration, as with dreams (Mavromatis, 1987).

Hypnagogic images seem to have been a critical factor in chemist Friedrich August Kekule's conceptualization of the structural formula of the benzene molecule as well as a Ludwig van Beethoven composition obtained while napping in his carriage en route to Vienna. William Blake claimed that images of spiritual beings, which started coming to him as a child, served as the basis for many of his later drawings. Thomas Edison often stretched out on his workshop couch; during these "half-waking" episodes, he claimed that he was "flooded" by creative images. Mary Shelley disclosed that her classic tale, *Frankenstein*, came to her as a series of hypnagogic images the evening after her group of friends agreed to compete for the best original Gothic horror tale (Shelley won).

Creativity and Daydreaming

Autobiographies and biographies reveal that several prominent individuals apparently utilized various types of daydreaming for creative purposes. Isaac Newton claimed to have solved many vexing problems in physics when his attention was waylaid by private musings.

The composer Claude Debussy used to gaze at the river Seine and its playful reflections of the sun to establish an atmosphere for his creativity. The writer Friedrich Schiller kept rotten apples in his desk drawer, stating the aroma helped evoke creative reverie. The philosopher John Dewey observed that creative conceptions frequently occur when people "are relaxed to the point of reverie." Jerome Singer (1966) found evidence in both children and adults of frequent daydreaming among those whose written or dictated stories were rated by judges as the most original and creative. Singer also reported that daydreaming was marked by passive, effortless indulgence of a wish in fantasy an uncritical condition typical of some types of creativity.

Cross-Cultural Comparisons

The way a culture conceptualizes creativity restricts it to some social practices and processes and denies it to others. During the heyday of Maoist thought in China, creativity was a matter of teamwork, and no individual artisan was allowed to sign a painting, claim authorship for an orchestral piece, or register credit for an invention. For spiritual reasons, the composers of Indian ragas did not affix their names to their works, and, in the Benin culture, the African deity Olokun is thought to influence artists through dreams and reverie. There are several societies in which specialists are encouraged to put aside their rational problem-solving modes of thought so that divinities may work through them.

Creativity, Meditation, Hypnosis, and Mediumship

There are psychophysiological markers for hypnagogia, hypnopompia, and napping. In the case of meditation, several studies have identified markers such as reduced respiration rate and volume of air breathed, reduced oxygen consumption and carbon dioxide elimination, and reduced blood lactate. In these studies, heart rate and the skin's electrical conductance decreased, but the frequency of alpha (and sometimes of theta) brain waves increased. All of these suggest reduced energy metabolism, autonomic nervous system arousal, cortical energy metabolism, and autonomic nervous system and cortical arousal. Reduced arousal during meditation is due to its rest and relaxation aspects rather than to the specific meditation practice employed. However, it is probably more accurate to speak of "meditative states of consciousness" than to hypothesize a single "meditative state," because different practices may emphasize rapid breathing and active movement rather than counting breaths, repeating phrases, focusing on a mandala, or witnessing to one's thoughts (Csikszentmihalyi, 1996).

The term "hypnosis" refers to a variety of structured, goal-oriented procedures in which the suggestibility and/or motivation of an individual or a group is enhanced by another person (or persons), or by oneself. These procedures attempt to blur, focus, and/or amplify mentation (e.g., imagination and intention), leading to the accomplishment of specified behaviors or experiences that reflect expectations and role enactments on the part of the "hypnotized" individuals who attend (often with little awareness) to the interpersonal or situational cues that shape their responses. Other research data emphasize the part that attention plays in hypnosis, enhancing the salience of the suggested task or experience. Both these bodies of hypnosis literature stress the interaction of several variables, suggesting that there are great individual differences in hypnotic responsiveness. Some participants are fantasy-prone, others dissociate easily, and still others are highly motivated to be "hypnotized." Both hypnotic susceptibility and creativity

are fairly stable personality traits, as measured by several standardized tests. The research on hypnosis and creative phenomena has shown that fantasy and absorptive experiences are concomitants of various changes in consciousness, including those due to hypnosis. They occur spontaneously in the context of a creative act; and they are often experienced by creative participants who, as a group, seem more adept than their less creative peers at shifting cognitively from a higher to a lower level of psychic functioning – from a more active to a more passive condition. In addition, the ability to tolerate unusual experiences and become absorbed in a variety of experiences correlates highly with hypnotic susceptibility. Time distortion in hypnosis has been used to facilitate the expressive arts and creative writing (Cooper and Erickson, 1954). Benefits from hypnotically enhanced rehearsals have been reported by actors and performing artists (Shames, 1992).

Because of the link between hypnosis and creativity, practitioners need to know with what degree of facility a hypnotized subject can produce pseudo-memories. Even if the increase in memories later is found to be accurate, it is often accompanied by an increase in inaccurate memories. These pseudo-memories attest to the participants' creativity but are often used inappropriately in psychotherapy.

The term "meditation" (from the Latin *meditatio* or thinking over) refers to a variety of practices that are used to self-regulate one's attention. All meditative practices attempt to bring the meditator into the "here and now," breaking through habitual phenomenological patterns. The case for increased creativity during meditation rests on the practice's ability to assist the meditator to break through socially ingrained patterns of perceiving and conceptualizing the world (Murphy and Donovan, 1988). If the linear, cause-and-effect way of thinking can be transcended, creativity may result. Creativity may be further enhanced by adopting a more circular way of thinking in which the focus is on relationships, possibilities, and recursive patterns rather than on linear causality and single-outcome events (Csikszentmihalyi, 1996). The research on meditation and creativity has produced mixed results. One group of researchers found no relationship between creativity test scores and experience in meditation. Another group reported significant increases in creativity scoring among practitioners of transcendental meditation (TM) and among Zen meditators. One of the latter studies focused on students of Zen koans, finding that they were able to eliminate prior approaches interfering with problem solving and enhance the unification of contradictory events.

Patricia Carrington has reported several cases of students whose grades have improved, whose emotions have stabilized, and whose artistic productions have flourished following their initiation of a meditation practice. At the same time, in a comparison of a group of teachers of TM with a group of non-meditators, the former did no better than the latter on most measures, worse on a few measures, and better on one measure – an open-ended task requiring them to make up a story. It seems that meditation may enhance the free flow of associations and evoke new ideas for a meditator, but an abundance of meditation (probably the case with the group of teachers) may interfere with a person's logical problem-solving capacity. A meta-analysis of all existing studies of TM and "self-actualization" concluded that the magnitude of the effects was not due to expectation, motivation, or relaxation, but to TM practice itself (Carrington, 1978).

Chico Xavier was a Brazilian medium who claimed to receive information from deceased persons ("spirits"), most of whom he had never met. By the time that he died in 2001, Xavier had written thousands of letters and nearly 500 books, all purportedly dictated by "spirits." A linguistic analysis of several of these books found no underlying similarities among the purported authors or with the writings of which Xavier claimed ownership (Playfair, 2010). Occasionally, someone who is not a professional medium will produce poems, essays, and books through automatic writing. In 1913, a Missouri housewife, Pearl Curran, was using a Ouija Board when a message arrived from "Patience Worth" who allegedly lived in the 18th century. Over two decades, Curran produced over 400,000 words "dictated" by Patience Worth. Some were historical novels that received acclaim from both literary critics and historical scholars. Curran wrote a detailed phenomenology of her "automatic writing," describing how images came to her while she was fully aware and never in a "trance" state.

Cross-Cultural Comparisons

Eastern and Western meditative practices have a long history; they have been viewed as spiritual exercises – means for attaining the special kind of awareness that can be arrived at in concert with other life practices. In contemporary industrialized societies, however, meditation tends to be oriented toward practical goals, with no ties to a specific belief system. The advantage is that one is free to use meditation outside a spiritual context, combining it with other methods of self-development and health-oriented or psychotherapeutic treatment. The disadvantage is that one may not attain the peace of mind of the unitive "bliss" claimed by members of traditional meditation schools.

The history of hypnosis is more recent. In the middle of the 19th century, James Braid introduced the term "neuro-hypnotism" or "nervous sleep" (from the Greek *hypnosis*, or sleep). However, the roots of hypnosis reach back to tribal rites and the practices of shamans. Hypnotic-like procedures were used in the court of the Pharaoh Khufu in 3766 BCE.; priests in the healing temples of Asclepius induced their clients into "temple sleep," and the ancient Druids chanted over their clients until the desired effect was obtained. Herbs were used by native shamans to enhance verbal suggestion in pre-Columbian Central and South America. It is, nonetheless, incorrect to label these procedures "hypnosis" simply because they drew upon similar procedures such as suggestion, repetitive stimuli, and client expectations. People, groups, and cultures are "creative" during those periods of time when they exhibit activities that are innovative for that specific group in ways it considers valuable. These novel concepts, objects, and behaviors (e.g., a scientific discovery, a mathematical theorem, a philosophical insight, an artistic masterpiece) can be considered creative, although one social group might arrive at a consensus different from that of another group.

The practice of mediumship varies from culture to culture. The enslaved Africans brought their religions with them to the New World. Since such practices were vigorously opposed by Christian clerics, they went underground. This was a successful strategy in the French, Spanish, and Portuguese colonies; currently, mediumship is being practiced in New Orleans, the Caribbean, and Brazil, often in a temple that represents a syncretic religion (such as Candomblé or Santería). Some church members are renowned for “incorporating” famous artists, selling the artwork both to local people and to tourists.

Neurophysiological Mechanisms

Art involves the controlled structuring of a medium or material to communicate as vividly as possible the artist’s personal vision of experience. If the Product (one of the “Four Ps”) resonates with a larger public, it has succeeded in filling some gaps in social knowledge or in resolving cultural contradictions. Artists also attempt to supply missing information or material in a culture’s legacy. The same can be said for those creative individuals who work with institutions and groups of other people. None of this labor is done in a vacuum; there are neurophysiological predispositions interacting with social and psychological variables in the development of a Product, Process, Person, or Place that is eventually deemed creative.

There are several perceptual mechanisms ordinarily driven by sensory input during one’s baseline state of consciousness that are decoupled, totally or partially, from sensory input during many alterations in consciousness. A total decoupling takes place during dreaming, while partial decouplings take place in hypnagogic or hypnopompic states, daydreaming, meditation, and some drug-induced or hypnosis-induced conditions. Transitions from such states represent a fertile ground for the development of creative ideas, because the perceptual mechanisms automatically linked to organizing the sensory inputs still occur, occasionally constructing novel and useful images from fragments of internal neural noise and loosely guided consultations with memory. Language allows the abstract images and relationships to be translated into a communicable form (Fink et al., 2009).

There is a direct relationship between perceptual processes and creative thought. The decoupling of normal sensory input during changed consciousness can be viewed as distinct from restricting sensory input in an individual’s ordinary waking state.

Psychosocial Mechanisms

The forms in which creative experiences are expressed cannot be separated from individuals and their cultures. Cross-cultural research has demonstrated that patterns of expectation within a given culture have an *a priori* influence on creative experiences. Thus, in those cultures where women are devalued, there is little opportunity for their creativity to be expressed and appreciated.

The effects of psychedelics upon creativity depend on more than their neurophysiological effects, which are produced by an interaction between pharmacological drug factors (type or dose), long-term psychosocial factors (culture, personality, attitudes, knowledge, beliefs, prior experience), immediate psychosocial factors (mood, expectations, group ambience), and situational factors (setting, instructions, implicit and explicit demands). For example, anthropologists who have observed the effects of *ayahuasca* among indigenous people in the Amazon comment that the phenomenology differs, sometimes strikingly, according to the environmental and ceremonial background against which the drug is taken, the ingredients used in its preparation, the amount of it imbibed, and the expectancies on the part of the participant.

Learning From the Past

The formal study of creativity dates back only to J. P. Guilford’s 1950 presidential address to the American Psychological Association, in which he urged his colleagues to pursue this overlooked area. After the connection between changed states of consciousness and divergent thinking was made, and investigations of the links among drugs, hypnosis, and creativity ensued, studies of additional altered and transitional states followed.

A seminal research project was undertaken by R.K. Siegel (1977). He conducted a systematic study of visual images produced by a variety of drugs, focusing on such varied dimensions of these images as color, movement, action, and form. Siegel’s participants were trained to use an image classification system prior to the drug sessions. There were baseline and placebo sessions for comparative purposes. Regarding reported images, the amphetamine (a stimulant) and phenobarbital (a sedative) sessions did not differ from placebo sessions. However, the sessions with mescaline, LSD, psilocybin, and a marijuana derivative produced similar images. In the psychedelic drug sessions, for example, complex images did not appear until well after there was a shift to lattice tunnel forms; memory images emerged in the later stages of the appearance of complex imagery. Noting that hypnagogic and hypnopompic images were accompanied by theta and low-frequency alpha brain waves, other researchers used biofeedback to teach participants how to obtain this phenomenology. There was an expected increase in the participants’ awareness of internal imagery and dream recall. What was unexpected was that most of them reported an increase in “integrative experiences” and “feelings of well-being.” These positive changes were amenable to intuition, insight, and creativity.

Several questions regarding the research on hypnosis and creativity remain unanswered. Robust findings are lacking due to methodological differences in the studies, the varied hypnotic responsiveness of the participants, and the disparate ways that creativity has been measured. Even when similar tests are used, they are administered differently, and the tests themselves admittedly assess a single instance or aspect of creativity. It may be that restrictions in awareness increase the priming of associative networks (outside of one’s awareness) by reducing cognitive interference. As a result, new associations are made, giving rise to creative insights.

Imagination or fantasy provides a continuous backdrop to mentation outside of awareness, and hypnosis may increase its accessibility. Heart rate probably reflects shifts of attention from external to internal events, making it a potentially revealing way to assess the oscillation of attention from an external focus of concern toward the internal events it triggers, a process that is one aspect of creativity. A significant relationship has been reported between heartbeat rate variability and participants' creativity scores, as more creative persons tended to show higher cardiac variability.

The psychophysiological studies of Zen meditators and yogic meditators revealed basic differences: members of the former group demonstrated "openness" to external stimuli, but were not distracted by them, whereas members of the latter group demonstrated "detachment" from external stimuli. In the light of this diversity, it is important that the type of meditation studied be identified in the assessment of phenomenological accounts, as well as the length of time the participants had been meditating. Further, it is common for meditation to blend into sleep during an experiment; hence, the images reported may be the result of hypnagogia or hypnopompia and not meditation itself. The application of chaos theory to the study of creativity has produced several insights, among them a description of how chaotic activity patterns in the brain can reconcile convergent and divergent problem-solving processes, and how "chaotic attractors" can utilize the brain's neural networks to combine images and thoughts that would escape detection during wakefulness.

Planning for the Future

It is customary to study "the four Ps of creativity": product, process, person, and place (sometimes called press). Simonton added a fifth P, persuasion. And this entry has added another "P," namely, phenomenology. One's experiences, whether ordinary, altered, or transitional, often play a key and pivotal role in evoking creativity as well as sustaining creative behavior.

Future research might identify the extent to which individual differences determine the scope of creativity. Such data could provide a better grasp of the degree to which information processing in altered or transitional states constitutes a major source of creative productivity. Mental constructions occurring during such states can be useful only insofar as they are remembered in order to be evaluated for application and utility. It may be that the degree to which decoupled automatic perceptual processes contribute to creative output has far more to do with facility in higher-level cognitive processes (such as memory storage and retrieval, search, and comparison) than in individual differences in the perceptual organization processes themselves.

One common view of why individuals manifesting some of the streams of schizophrenic-like thought might be viewed as creative is that deficiencies in their customary involuntary perceptual organization processes lead to an increased likelihood of an atypical representation of a perceptual event. In other words, it may be the anomalous organization of sensory input, coupled with sufficiently appropriate higher order processes to evaluate the potential value of a mental construction, that lead to creative output. Creativity attributable to looseness in perceptual organization in the presence of stimuli is very different from creativity attributed to perceptual organization processes decoupled from normal sensory inputs. An increased frequency of transitions from transitional states of consciousness, as might reasonably be expected to occur in association with certain psychotic disorders, may be combined with unimpaired, or even superior, mechanisms of perceptual organization. This would represent a potential alternative route for contributing to creative thought by those individuals who are disposed toward cognitive disorders. Moreover, the relative instability or looseness in organizational processes, in tandem with the ability to exploit involuntary organizational processes decoupled from sensory input, may display individual difference variables. In this regard, what Richards (2018) has dubbed "everyday creativity" is an overlooked phenomenon in a field that all too often emphasizes the exotic, the dramatic, and the spectacular. It is quite likely that creative work draws more upon the ordinary waking state with its intact subsystems of consciousness than upon altered and transitional states.

Drugs can be ingested, meditation can be practiced, hypnosis can be utilized, and the contents of reverie can be recorded, but everyday behaviors and experiences can also provide inspiration for what later may become a novel approach to a long-delayed home refurbishing, an improved golf stroke, a new recipe for a family dinner, a breakthrough in a troubled relationship, an ingenious plan to divert restaurant leftovers to homeless people, a challenging educational technology, or any one of many other achievements.

The need for creative approaches at all social levels, as well as from all phenomenological states, has never been greater. Their development and application need to reflect the concepts of "origin" and "making," which have so appropriately grounded the Latin word *creare*.

Creativity has been defined in different ways by different investigators. The standard definition of creativity, however, holds that creativity involves the production of original, high quality, and elegant solutions to complex, novel, ill-defined, or poorly structured, problems. The need to produce solutions to novel problems, albeit, potentially problems that are only novel to the particular person engaged in the problem-solving effort, has an important, often overlooked, implication. To generate novel problem solutions, people must in some way formulate new knowledge to be used in generating original ideas for problem-solving.

This straightforward observation, however, begs a new question – one fundamental to understanding creative thinking. How do people go about formulating new knowledge? The answer most commonly provided to this question is new knowledge is created through the combination and reorganization of extant knowledge structures (Finke et al., 1992). Although the bulk of the available evidence supports this proposition (e.g. Mobley et al., 1992), yet another question arises. Exactly how do people go about combining and reorganizing extant knowledge structures? In other words, what are the cognitive operations involved in conceptual combination and reorganization?

Although many operations might be involved in conceptual combination and reorganization, it appears the key mechanism involved is analogical reasoning. Analogical reasoning involves identifying the *similarity* between multiple objects, events, or knowledge structures. In its' most simple form, analogical reasoning involves a statement A is similar to B based on this, or these, shared features, or attributes, of the objects of concern. For example, Zeus is to Jupiter as Venus is to _____. Aphrodite is the correct answer if one assumes the feature here is Greek and Roman gods. In the present effort we will examine how analogical reasoning contributes to conceptual combination efforts.

Analogy used in cognitive processing give rise to structuring and mapping activities necessary in complex problem-solving efforts. Gentner et al. (2001) discuss the use of mapping and analogical reasoning when generating mental models, a cognitive product used to make sense of the world. Moreover, the use of these analogies, particularly the use of multiple analogies, seems critical to reasoning and problem-solving efforts, as they enhance understanding of complex phenomenon.

Additionally, it appears analogical reasoning contributes to problem-solving efforts across multiple domains. Work by Sternberg and Nigro (1980) suggests that strategies employed may differ across individuals, perhaps due to expertise, but that analogies are beneficial for problem-solving regardless of the context. Thus, one might expect analogies to be beneficial in contexts calling for creative problem-solving.

Knowledge

Seeing similarities between concepts or events, of course, requires knowledge bearing on those concepts or events. In fact, a wide variety of studies have shown knowledge, or expertise, is, in fact, critical to creative performance. In one study along these lines, Vincent et al. (2002) asked some 1800 military officers to solve a set of military problems calling for creative thought where judges appraised the quality and originality of problem solutions, along with officer's ability to address critical incidents arising in the course of their work and their success in executing various creative thinking processes. Expertise was measured by asking participants to sort tasks into relevant leadership concepts and the accuracy of these task sorts was established based on their similarity to a theoretical model of military leadership. It was found this measure of expertise, along with measures of intelligence and divergent thinking, contributed, strongly contributed, to execution of various creative problem-solving processes, and in turn, contributed to production of creative problem solutions, original and high-quality solutions, as well as subsequent critical incident performance.

Although studies have demonstrated the impact of knowledge on creative problem-solving, they do not speak to the content of the knowledge people use in solving creative problems. This issue has been addressed in a study by Hunter et al. (2008). In this study, undergraduates were asked to develop a new course intended to prepare high school students for college where judges appraised the quality, originality, and elegance of these course proposals. Prior to working on these course proposals, however, participants were primed, through instructional manipulations, to use schematic, or conceptual, knowledge, case-based, or experiential, knowledge, or associational knowledge. It was found the most creative problem solutions emerged when people used conceptual knowledge or case-based knowledge in problem-solving, or a combination of conceptual and case-based knowledge.

Processes

Of course, if available concepts and cases allowed people to solve problems unto themselves, there is no need for creative thought. Instead, in creative problem-solving, it is held extent knowledge must be reshaped, or reformed, to produce viable solutions to novel problems. Accordingly, a key question confronting students of creativity has been how do people work with knowledge to produce novel problem solutions? The ways people work with knowledge in problem-solving has been discussed in terms of creative thinking processes. Over the years, many models of peoples creative thinking processes have been proposed.

Mumford and colleagues (e.g., Mobley et al., 1992) reviewed the various models of creative thinking processes that had been proposed over the years. They identified eight core processes commonly proposed in these models: 1) problem definition, 2) information gathering, 3) concept/case selection, 4) conceptual combination, 5) idea generation, 6) idea evaluation, 7) implementation planning, and 8) adaptive monitoring. Each process produces products needed for successful execution of the next process. And, execution of any given process was held to involve multiple cognitive operations with some operations, for example identifying procedures in problem definition, contributing to more effective process execution and thus better creative problem-solving. Execution of each process, moreover, was held to require evaluation of product outputs with people cycling back to earlier processes if an output was found to be inadequate.

In an extensive, ongoing, set of studies Mumford and his colleagues have acquired a substantial body of evidence supporting the validity of this process model (e.g., Mumford et al., 1997a). Broadly speaking, the findings obtained in these studies indicate that 1) effective execution of each of these processes makes a unique contribution to prediction of performance on creative problem-solving tasks, 2) effective execution of these processes contributes to performance on creative problem-solving tasks drawn from multiple different domains of performance, 3) effective process execution is strongly related to creative problem-solving ($r = 0.50$ with reliabilities in the 0.70s), 4) effective process execution adds to the production of creative problem-solving performance above and beyond standard abilities such as intelligence and divergent thinking, 5) each process involves multiple mental operations – thus in information gathering people must search for facts and anomalies with respect to these facts, 6) errors flow through these processes – thus an error made in problem definition disrupts information gathering, and 7) effective execution of these processes depends not only on mental operations but also the nature of the knowledge on which these operations are executed.

This model is noteworthy for a number of reasons. For example, it indicates idea generation occurs relatively late in a cycle of creative problem-solving activities. It implies idea evaluation is an active, constructive, process requiring self-criticism and reflection. Perhaps, most centrally, it suggests that the new knowledge needed to propose solutions to novel problems arises from, or is based on, the conceptual combination process.

Conceptual Combination

In an initial set of empirical studies into the role of conceptual combination in creative thought, Maier and Thurber (1970) presented undergraduates with fragmented word pairs (e.g., shoe, glove) and asked them to combine these words to generate a story. They found that participants regrouped and reorganized these words to generate creative stories. Moreover, creative stories based on these word combinations could not be accounted for by simple word preference.

Somewhat more recent evidence bearing on this importance of conceptual combination in creative problem-solving was provided in a study by Mobley et al. (1992). They presented undergraduates with 15 category combination problems. On these

problems, participants were presented with three taxonomic categories defined by four exemplars of this category (e.g., birds, robins, sparrows, owls, ostriches). They were asked to combine these categories to generate a new category, provide a label for this new category, provide additional examples of category members, and write a story using this new category. Judges were asked to appraise the originality and quality of the new categories formulated in this category combination task.

In working through these conceptual combination problems, two studies were conducted where various manipulations occurred in the nature of the material presented. Category similarity was manipulated, category content (e.g., biological or artifactual) was manipulated, and exemplar typicality (e.g., robin vs ostrich) was manipulated. It was found that presentation of more diverse categories and categories defined by atypical exemplars resulted in the production of more creative new categories, more creative category exemplars, and more creative stories. Thus conceptual combination does appear to contribute to creativity.

Confirmation of this observation was provided in another set of studies by [Finke et al. \(1992\)](#). In these studies, participants were presented with a number of different shapes – for example a hook and a block. They were asked to combine these images in such a way as to create new tool. It was found that skill in combining these images was positively related to the creativity of the new tools produced. Moreover, certain conditions were found to influence the production of more creative new tools – for example asking participants to think about applications or asking participants to elaborate on their initial designs.

In fact, these findings are in no way unique. [Owens \(1969\)](#) attempted to develop a test to select engineering students for creativity. On this test, participants were presented with mechanical objects (e.g., gears) and power sources and asked to combine these parts to design a new machine. What is of note is scores on this domain specific measure of conceptual combination proved strongly ($r = 0.40$) related to standard measures of creativity in engineering such as patent awards. Thus conceptual combination not only exists as a unique processing activity, it appears to be a viable predictor of creative achievement.

Analogies

[Baughman and Mumford \(1995\)](#) sought to identify the key analogical reasoning operations people must execute as they seek to combine and/or reorganize given knowledge to create the new knowledge needed for idea generation. More specifically, they argued that conceptual combination requires 1) a search for key features of each category, 2) mapping of shared and non-shared features of each category onto each other, 3) combination of shared and non-shared features, and 4) elaboration on new features arising from combinatory activity.

In the [Baughman and Mumford \(1995\)](#) study, participants were asked to solve a series of category combination problems drawn from [Mobley et al. \(1992\)](#). After generating their new category, participants were asked to provide a label for this category and generate a list of additional exemplars of this new category. Judges appraised new category labels and exemplars for quality and originality. As participants began work on these problems, however, they were presented with instructions to encourage feature search, feature mapping, feature combination, and elaboration under conditions where more or less similar categories were presented.

It was found that feature search, search for shared and non-shared features, of the stimulus categories and mapping of shared and non-shared features of these categories, contributed to the production of higher quality, and more original, new categories and category exemplars. It is of note, however, these effects emerged only when feature search and feature mapping occurred in tandem – participants were instructed to do both the search and mapping operations. And, it was found that elaboration on the new features of the category emerging from conceptual combination also contributed to production of more creative solutions. Finally, these effects were strongest when people were presented with more, as opposed to less, similar categories.

These findings are noteworthy because they suggest analogical reasoning may underlie successful combination and reorganization efforts. By the same token, however, the [Baughman and Mumford \(1995\)](#) study leaves two questions unanswered. First, does effective execution of these operations, search, mapping, combination, and elaboration, result in production of more creative problem solutions? Second, how do these operations occur when people are presented with more diverse categories? Answers to both these questions have been provided in a study by [Mumford et al. \(1997a\)](#).

In the [Mumford et al. \(1997a\)](#) study, participants, undergraduates, were asked to produce advertising campaigns for a new product, the 3D-holographic television, and solve a public policy problem, a recycling problem, both calling for creative thought. Judges appraised problem solutions for quality and originality. Prior to preparing their problem solutions, however, participants were presented with a set of category combination problems drawn from [Mobley et al. \(1992\)](#) where the quality and originality of the new category labels, new features, and category exemplars were appraised. In addition, category similarity was manipulated under conditions where people were, and were not, asked to think about metaphors – global concepts allowing similarities to be identified in feature search and mapping.

The findings obtained in this study indicated that category labels, features of the new category, and new category exemplars were strongly, positively, related ($r = 0.45$) to the quality and originality of the solutions provided to both creative problems. Thus, there is reason to suspect that feature search and mapping operations of analogical reasoning do contribute to creative problem-solving. Moreover, when people are presented with more diverse categories, instructions to think about metaphors contributed to better conceptual combination and thus better creative problem solutions.

In a third study along these lines, [Scott et al. \(2005\)](#) asked undergraduates to formulate plans for leading a new experimental secondary school. Judges appraised the quality, originality, and elegance of participant solutions to this problem. Prior to starting work on this problem, participants were presented with either concepts derived from prior research on cooperative learning

techniques or actual cases where cooperative learning techniques had been deployed. Moreover, the number of concepts presented (10 vs 20) and the number of cases presented (2 vs 4) was manipulated. As people worked through the concepts presented they were instructed to identify critical features, list feature similarity and differences, combine features, and elaborate on new emergent features. Written answers to the probe questions associated with these instructions were appraised by judges for quality.

It was found the quality with which people executed the search, mapping, and combination, and elaboration operations was strongly, positively, related ($r = 0.45$) to the quality, originality, and elegance of solutions to this creative problem. And, moreover, these relationships became more powerful when people were asked to work with a larger number of concepts in creative problem-solving. Thus the analogical feature search and mapping operations in conceptual combination do apparently, contribute, and contribute strongly, to the production of creative problem solutions.

The Scott et al. (2005) study, however, also provided instructional primes when participants were asked to work with case-based knowledge in conceptual combination. Here, participants were asked to identify the key characteristics of each case, list the strengths and weaknesses of each case, combine the strengths of each case to create a new case model, and forecast the implications of actions given this model. The first finding here was that the most original, highest quality, and most elegant solutions emerged when people worked with fewer rather than more cases in conceptual combination. This finding was not especially surprising, however, because the complexity of case-based knowledge structures makes it difficult for people to work with a large number of cases in feature search and mapping. More centrally, however, the nature of the feature search and mapping operations differed. When case-based knowledge was employed in conceptual combination, feature search and mapping operations became pragmatic, action centered, mappings focusing on attributes of the case leading to success and forecasting the likely success of alternative actions when elaborating the new case model.

These observations are noteworthy for three reasons. First, analogical reasoning mechanisms appear to condition the success of conceptual combination efforts and thus the success of subsequent creative problem-solving efforts. Second, the specific cognitive operations occurring in analogical reasoning differ as a result of the basic nature of the knowledge being used in conceptual combination. Third, use of different knowledge structures in conceptual combination allows people to work with more, or less, distinct types of knowledge.

Search and Mapping

Nonetheless, our foregoing observations suggest that regardless of the type of knowledge under consideration, analogies that promote feature search and mapping, and elaboration on emergent features, provide the basis for conceptual combination and thus impact the success of peoples creative problem-solving efforts. This observation, in turn, breaches three new questions. First, how are key features identified? Second, how are these features mapped to appraise similarity and differences? Third, how does elaboration on emergent, new, features occur? Answers to all three of these questions appear to depend on the nature of the knowledge the person is working with in creative problem-solving.

The identification of key features when people are using case-based, or experiential, knowledge can be traced to the fundamentally pragmatic, action oriented, nature of case-based knowledge. More specifically, elements of case-based knowledge structures held to determine the attainment of significant affordances, good or bad outcomes, are likely to be viewed as key features of any problem solution. Greater weight, however, may be given to actions associated with positive as opposed to negative outcomes. In this pragmatic framing, moreover, constraints that act to limit actions are likely to be perceived as significant features of the problem.

When schematic, or conceptual, knowledge is employed in problem-solving, significant features are most likely to be identified using the general mental model people employ for understanding problems in a given domain. The mapping of features when schematic knowledge is in use will typically be based on integrating concepts relevant to the problem into an overarching model. At times the number and diversity of the concepts involved may make such integrative thinking difficult. Under these conditions, people may employ metaphors to help in concept mapping.

When mapping occurs using case-based knowledge, however, a rather different method will be employed. Strange and Mumford (2005) have shown creative problem solutions are often tied to plans. And, when case-based knowledge is employed, idealized, or prescriptive, plans may provide the key framework used in concept mapping. Often this will require not only identifying key causes and goals appearing in all cases, but also identifying the constraints that might allow these causes and goals to operate in one setting, or case, as opposed to another setting or case (Medeiros et al., 2014). Thus constraints on actions may prove especially important in mapping features when case-based knowledge is used in conceptual combination.

When case-based knowledge is being used in conceptual combination we have a reasonably sound understanding of how elaboration occurs. More specifically, elaboration appears to depend on extensive forecasting when case-based knowledge is employed in conceptual combination. In fact, a study by McIntosh, Mulhearn, and underscores this point indicating that more extensive forecasting is strongly positively related ($r = 0.40$) to idea generation – a key outcome of conceptual combination.

When conceptual knowledge is employed, elaboration appears to proceed using somewhat different mechanisms. One key mechanism is extension of new emergent features to incorporate new exemplars and differentiate this emergent feature from other relevant features. Another key mechanism underlying effective elaboration, when conceptual knowledge is in use, may be found in embedding a new emergent feature in extant mental models – linking this feature to other causes, mediators, moderators, or outcomes embedded in the mental model people use to understand problems arising in a certain domain.

Conclusions

Our foregoing observations with regard to search, mapping, and elaboration operations of analogical reasoning are noteworthy because they provide some important clues about how we might seek to develop people's capabilities for effective execution of the conceptual combination process. For example, one might encourage people to think about metaphors when working with diverse concepts. One might ask people to forecast extensively and carefully evaluate the implications of their forecasts. One might ask people to think about how emergent new features could act as a cause in different models for understanding problems arising in a domain. These, and other potential interventions arising from understanding how analogical thinking occurs in conceptual combination point to a noteworthy, broader, conclusion. Understanding the key operations contributing to effective execution of creative thinking processes provides the basis for formulating a number of new approaches for the development of creative capacity.

The present effort by demonstrating how analogical thinking, search, mapping, and elaboration operations, contribute to conceptual combination provides an illustration of this point. The present effort, however, also serves to remind us that the specific operations occurring in process execution depend on the type of knowledge people are working with in process execution. Hopefully, the present effort will provide an impetus for future work intended to specify how the nature of the knowledge people are working with in process execution shapes the operations required for effective execution of various creative thinking processes.

Human Beings: The Creative Species

Anthropological studies show that human beings have displayed creativity from the earliest times. Prehistoric decorative creativity included paintings and drawings, carvings, engravings and sculptures, involved media such as rock surfaces, stone, clay, or bone, encompassed products such as, decorations, figurines, jewelry, or even musical instruments, and consisted of both immobile (e.g., wall decorations) and portable (e.g., figurines, jewelry) works. However, prehistoric creativity was not confined to aesthetic products such as those just listed, but also involved novel tools and life-preserving or life-enhancing daily-use objects such as hunting spears, hand-held scrapers for treating hides, axes, agricultural machinery, water control systems, sewn clothing, and purpose-built dwellings. Such non-artistic products are often referred to as involving innovation, but they will be treated in this entry as examples of what I call 'functional' creativity (Cropley and Cropley, 2005, p. 169). In fact, creativity has been of such core importance from the earliest times that, in the words of Puccio (2017, p. 331): 'The survival and expansion of the human species is fundamentally a story of creativity.'

Terminology

Because the term 'creativity' only began to be used in the English language in the modern sense in about 1875 and there is still disagreement concerning its exact definition, the concept will be understood in this entry in a broad way. The focus will be on the generation of novelty that is in some way useful. Furthermore, useful novelty will be treated as encompassing a wide range of activities and fields, both aesthetic (fine art, music, literature and the like) and functional (e.g., science, engineering or commerce). Rudimentary psychological analyses of what is now called creativity have survived since at least around 3500 BCE (i.e., from the emergence of writing), and have left insights into how it was conceptualized in the distant past. Consequently, the period from about 5000 to about 2000 years ago will define the term 'ancient' for the purposes of this entry.¹

The Purpose of the Entry

The purpose of this entry is not to provide lists of the creative achievements of ancient civilizations, to determine exactly where and when specific creative products first came into use, or to evaluate the precise contributions made by early creative individuals. The entry is also not concerned with what factors in a society – such as the availability and nature of role models, the form of government, or the level of social and political stability – caused, shaped or facilitated/blocked generation of useful novelty in ancient societies. The key issue is how the societies conceptualized creativity and what purpose it was seen as fulfilling. For example,

- How did ancient societies regard creative products?
- How did they understand the process of generation of such products?
- How did they regard people who generated them?
- What was the nature of the environmental press acting on creative individuals?

This structure of the conceptualization of creativity is similar to the 4 Ps framework (e.g., Rhodes, 1961) that is widely accepted nowadays, and covers understanding of Product, Process, Person, and Press.

¹All dates given in this paper, including those in later sections, are rounded and approximate in the extreme. They are not given in order to locate events in exact historical terms, but merely to allow readers to orient themselves temporally.

Case Studies

As [Simonton \(2018\)](#) pointed out, the only way to gain the necessary insights into ancient creativity is to examine what went on in the societies in question. Consequently, brief case studies of four ancient civilizations in the Middle East, the Far East and Europe – Egypt, Mesopotamia, China, and Greece – will be used to cast light on issues such as motivation for the generation of novelty or the social pressures affecting creative people in those societies. These particular civilizations were not chosen by means of random sampling or on the basis of formal selection criteria (for example, that they have demonstrably had the greatest influence on modern thinking), but on the subjective basis that they represent a broad sample of ancient civilizations in which creativity played an obvious role and that a degree of knowledge about how creativity was conceptualized in these societies has survived. The conclusions drawn here are speculative interpretations only, and no claim is made concerning their replicability. The case studies represent extreme simplifications and generalizations about complex societies, so that the risk of stereotyping must be kept in mind.

Egypt (Focus: From Around 3000 BCE)

Music and performing arts, fine art, literature, but also clothing, jewelry, furniture, and architecture were all fields in which the Ancient Egyptians displayed aesthetic creativity. The reign about 3500 years ago of Hatshepsut (1478 BCE–1458 BCE), one of a very small number of female pharaohs, marked one highpoint of such creativity in Egypt: Her mortuary temple was ‘a showcase for creativity’ ([Galán, 2014](#), p. xi). In the case of functional creativity, the Egyptians invented new kinds of construction machinery and developed maritime technology. In manufacturing they developed new systems of mass production, for example for the production of pottery. In science they developed new knowledge in astronomy, mathematics, and medicine.

One striking aspect of Ancient Egyptian generation of novelty is the way the Egyptians understood the purpose of creativity: this was ‘cultural perpetuation’ ([Dorman, 2014](#), p. 1), not only in this world, but also in the next. The key concern of the society was preservation of the traditional way, and excessive novelty was regarded as a potential threat to eternal survival. Although the Egyptians linked aesthetic creativity to the gods, the works it led to were not seen as messages from the gods to human beings but, on the contrary, often contained instructions from humans to the gods, for example advising the deities what humans wanted in the afterlife. Creativity was thus a risky business, as it could send conflicting signals that might confuse the gods and have negative consequences for the rest of eternity. Thus, even in the aesthetic domain creative products in ancient Egypt had a clear utilitarian purpose and obeyed the ‘usefulness imperative,’ which [D.H. Cropley and Cropley \(2015, p. 21\)](#) see as an indispensable property of modern engineering or commercial creativity. Ancient Egyptian creativity was ‘demand-side’ creativity – those on the receiving end dictated what purpose creativity had, what kind of novelty was to be generated, at least in broad terms, and how novel it was permitted to be, and the generators of effective novelty worked within that framework.

The creative process was understood as skilled repetition of known procedures in order to polish – not fundamentally alter or replace – what already existed, and the quality of creative works was mainly determined by their level of artisanship. The Ancient Egyptians sought inspiration from the past, and the source of ideas was mainly existing knowledge and custom. Nonetheless, individual experimentation did occur. However, in generating novelty it was essential to respect socially-imposed limits and change was limited to ‘gradual evolution’ ([Galán, 2014](#), p. x); it was incremental rather than disruptive, involving adding or modifying details, to be sure, but without changing basic forms. Aesthetic works were often carried out by teams, in which individual members were usually responsible for particular highly specific elements of every different work, over and over again. Thus, creative works were not normally attributed to a single extraordinary individual, although contemporary writings did not ignore the idea of personal creativity entirely. For example, [Spiegelberg \(1902\)](#) cites a tomb inscription which says of Meryra, the artist who decorated the tomb in question 3500 years ago: ‘He is not a draftsman; it is his own intelligence that must direct him.’ However, many aesthetically creative products were not intended for public consumption at all, as they were located in the tombs of the people who commissioned them, and the tombs were hidden away. Thus, creative superstars were largely non-existent, and the role of the imagination of the individual creative person was of limited interest.

Mesopotamia (Focus: From Around 3000 BCE)

The term ‘Mesopotamia’ is used here to refer to the region between the Tigris and Euphrates Rivers in the Middle East – more or less the area now known as Iraq. The discussion of creativity which follows encompasses successive dominant cultures in this region, especially Sumeria, Akkadia, Babylonia, and Assyria which, despite their differences, in the period from around 3000 BCE to about 500 BCE demonstrated a number of relatively homogeneous characteristics vis a vis creativity. Mesopotamian functional creativity led to the emergence of writing, which made possible the systematic recording of experience, for example in the form of detailed medical textbooks and new understandings in mathematics, science, astronomy and geometry, as well as codified law (Codes of Hammurabi). Mesopotamian physicians were aware of the importance of cleanliness and personal hygiene, and town planners incorporated this knowledge into the development of clean cities. In architecture and building technology architects and engineers invented the arch and the vault, metallurgists developed novel methods for alloying metals, carpenters developed new tools for woodworking and perfumers and potters developed industrial production processes such as the use of the potter’s wheel, which later led to wheeled vehicles. In agriculture, the Mesopotamians developed novel farming practices such as crop rotation and irrigation.

Aesthetic creativity included poetry, epic stories, fables, proverbs and songs. The recent invention of writing meant that the knowledge and wisdom of the past could be preserved in libraries to ensure that they could be read and consulted by successive generations. Unlike the other ancient cultures discussed above, Mesopotamian aesthetic creativity made a clear distinction between providing representations of what already existed – later regarded by the Ancient Greeks as imitating – and inventing something new: Where events, actions, processes or scenes from the real or mythological past were depicted, not just the technique of presentation but also the actual contents were frequently consciously and deliberately embellished or improved, while preserving the main message. Thus, the idea of artistic license emerged.

The Epic of Gilgamesh offers a striking example: Gilgamesh was an ancient king who ruled in Mesopotamia about 2800–2500 BCE. He first became a legend about 500 years after his death, initially in a number of Sumerian tales, of which five survive. A further 500 or more years later these tales were brought together in a single work by a single, identifiable Babylonian author, Šin-lēqi-unninni, who is regarded by some modern authorities as the creator of epic poetry. Although ancient Mesopotamian literature was largely anonymous, with only a very few well known authors, an intelligentsia emerged whose members clearly differed from mere copyists because they consciously embellished existing contents or invented additional content for literary works, rather than simply copying what already existed, i.e., they practiced artistic license. Such novel representations of events were understood to have their origins in the imagination of these creative individuals, and there was interest in the cognitive processes leading to the generation of fiction.

China (Focus: From Around 500 BCE)

Ancient Chinese functional creativity is commonly regarded as encapsulated in four great advances in science and technology: the compass, gunpowder, papermaking, and printing. One important aspect of these creative advances is that the Chinese went to great lengths to prevent novel technology from passing into foreign hands, although they were ultimately unsuccessful in this. Thus, the Ancient Chinese had an understanding of the commercial value of useful novelty in an international context, as distinct from its internal value in preserving their present, communicating with the gods, or preparing for the afterlife. However, gunpowder and the other discoveries and inventions mentioned above were developed very late in the period on which this entry focuses. Of greater relevance are more ancient examples of Chinese functional creativity in, for example, nutrition (e.g., the fermenting of alcohol and the brewing of tea), clothmaking (e.g., the cultivation and processing of silk), medicine (e.g., the development of acupuncture), metallurgy (e.g., the smelting of iron and the casting of bronze), or agricultural engineering (e.g., the invention of the seed drill).

In the case of aesthetic creativity, in the pre-Confucian era (before about 350 BCE) artworks were produced by anonymous artisans to satisfy the purposes of authoritarian feudal rulers. Creative ideas were shaped by the dictates and desires of the people in power at the time, so that the Ancient Chinese conceptualization of creativity was controlled by the ‘cultural climate’ (Staats, 2011, p. 45) and was largely limited to incremental innovation. At the very end of the period, the upper-class literati began producing music, calligraphy, poetry and painting on their own initiative, and such works became a sign of personal cultivation and education and an indication of individual powers of imagination and sensitivity. Thus, two conceptualizations of creativity existed side by side: the one encompassing the large body of work of the many nameless professional artisans who produced novelty at the behest of those in power (i.e., demand-side creativity), which was ‘almost exclusively imitating’ (Gabora and Tseng, 2017, p. 465), and the other focused on the small body of work of the cultured upper-class elites, who produced whatever pleased them (i.e., supply-side creativity, which was ‘almost exclusively inventing’). The former was seen as mere artisanship and was attributed to manual skill, not imagination; in the words of Edison (Josephson, 1959, p. 97), to perspiration rather than inspiration. The latter was attributed to the creative mind of its makers, and was a sign of cultural superiority, i.e., elitist. This two-track view of Chinese creativity has persisted until today, with many modern discussions focusing on supply-side creativity and the works of revered individuals, rather than on the far more extensive oeuvre of the usually anonymous producers of demand-side creativity.

Ancient Chinese aesthetic creativity initially depicted submission to higher powers – to the forces of nature and the will of heaven – but later began to express increasing understanding of the dictates of these powers and to promote proper moral and social values such as benevolence, virtue, loyalty, fidelity, or purity. Art and literature were thus expected to be beautiful, to be sure, but also to be edifying and socially instructive, i.e., not merely to depict the world but to show people what it ought to be like in an idealized form. Toward the end of the ancient era, the ideals of Confucianism greatly strengthened the ethically instructive role of creativity. Paradoxically, Confucianism is now seen as inhibiting creativity in modern Chinese culture, because of its emphasis on, for example, strict gender roles, rote memory and avoidance of uncertainty.

Greece (Focus: From Around 500 BCE)

Whereas in older civilizations artisanship was regarded as at the heart of creativity, in Ancient Greece making things through manual effort was a sign of inferior status. For example, although the Greek Phidias is still regarded today as a great sculptor, in Ancient Greece he was looked down upon, because he worked with his hands. This contempt for physical labor devalued functional creativity. Nonetheless, the Ancient Greek civilization provided many inventions and discoveries in applied fields, including for example mechanical engineering (e.g., gears, cranes and winches, the steam engine), hydraulic engineering (e.g., aqueducts,

storm-water drains, effective sewage systems), medicine (e.g., a variety of surgical instruments, methods for stopping bleeding and cleaning wounds), and daily-use objects (e.g., the alarm clock).

In the case of aesthetic creativity, in Ancient Greece visual artists were regarded as no more than skilled imitators of the real world, because they merely produced images of what already existed. Only poets were regarded as generating genuine novelty by writing about unseen or imaginary people or events and lofty feelings (such as Olympian rage or devastating sorrow). Thus, the Greeks differentiated sharply between people whose works were judged to be mainly imitating and those whose works involved mainly inventing. The core of creativity was not artisanship but novel ideas. Thus, in contrast to other ancient civilizations, the Ancient Greek conceptualization of creativity gave great prominence to individual people. Although there is doubt about whether Homer was a single writer or a legendary composite figure, names from the classical Greek period around 800 to 200 BCE, such as Aeschylus, Euripides and Sophocles (drama), Phidias (sculpture and architecture), as well as Hippocrates (medicine), Archimedes (engineering), or Pythagoras (mathematics) are even today almost household words. However, the motivation for creativity was regarded as lying outside the mind of the creative individual and reflecting the will of higher powers. Plato and Aristotle concluded that the chosen ones were forced to carry out their creative work whenever the divine powers acted on them because they were in the grip of what Plato called a 'divine frenzy' and Aristotle a 'tincture of madness.'

This conceptualization made creative individuals a breed apart from mere mortals, since they were messengers of the gods. In turn, this had important positive consequences for their social standing: they were prominent, highly admired figures in their society. Their celebrated creativity yielded handsome personal rewards, giving them what Deresiewicz (2015) called a 'sacred aura,' and entitling them to the benefits of a 'sacerdotal tax' (i.e., they enjoyed almost priestly status and were entitled to have their way of life financed by the general public). Thus, creativity came to be linked with chosen favorites of higher powers who developed unprecedentedly new ideas through personal inspirations granted to special individuals, not by preserving and skillfully expressing what already existed. (This veneration of creative superstars continued into Ancient Rome. For example, Horace (2005) (c.19 BCE, lines 9–10) pointed out that in Rome artists enjoyed special licence to do as they pleased.) Thus, Ancient Greek creativity was supply-side creativity with great emphasis on the idiosyncratic, god-given inspirations of revered talents.

Analytic Overview

The conceptualizations of creativity in the four ancient civilizations can be compared and contrasted in terms of broad themes, which can be summarized in terms of the well-known 4 Ps of creativity: Press (the social function of creativity), Product (the preferred kind of novelty), Person (the perceived role of the individual), and Process (embellishing what already exists vs. replacing it). The purpose of such a summary is not to provide an exact analysis of several thousand years of history in four different civilizations, but to use dimensions derived from the modern understanding of the psychology of creativity in order to give a broad idea of where similarities and differences between civilizations lay.

The conceptualizations of creativity in the ancient civilizations share common broad dimensions such as the idea that creativity has a role in the divine order of things. However, these do not form a homogeneous set of ideas that prevailed in more or less identical form across the ages and across cultures. For example, the Egyptians regarded aesthetic creativity as a way for humans to send messages to the gods, whereas the Greeks saw it as a way of receiving messages from the gods. The Egyptian society would not tolerate any fundamental change in the way human existence was depicted, as this would have threatened their eternal life by sending mixed messages to the gods, but accepted only technical embellishments to the presentation of this understanding (i.e., the message had to be always the same, although it could be presented more clearly or packaged more attractively). By contrast, the Mesopotamian society understood the need to change the fundamentals in order to achieve improved effects (poetic license), and the Greeks specifically demanded serious departure from the usual; otherwise products were no more than imitations.

Nonetheless, there seems to have been a discernable sequential change in the conceptualization of the Person from the almost completely anonymous artisan of the Egyptian civilization to the favorite of the gods of the Greek, with the rise of what I have called the "creativity superstar" emerging in stages, rather than all at once. In the case of understanding of Process, there seems to have been a similar step-by-step change in the acceptance of modification of already existing ideas, from the point where it was absolutely forbidden (Egypt) to the point where, in the Ancient Greek civilization, it was absolutely required. There appear to have been similar systematic developments in connection with Press (from social rejection of change to insistence on it), and with Product (a movement from skilled imitation of existing forms to creation of new forms). Experimental studies (e.g., Gabora and Tseng, 2017, p. 465), suggest that particular social conditions promote 'almost exclusively imitating,' whereas other conditions promote 'almost exclusively inventing.' Cross-cultural studies of the repercussions of increasing societal complexity demonstrate these effects in actual life, with artisans emerging long before artists.

Introduction

In humans, creativity is used for communication, expression, pleasure, courtship, problem-solving, and countless other activities. Some are of great urgency, whereas most are not. In the animal world, however, creativity is often literally a matter of life or death. Imagine a cane toad happily eating bugs and small creatures in the wilds of South America. One day, it is captured and flown off to Australia. When the toad hops out of its cage in a new country, it finds none of the bugs from South America with which it is familiar. Will the toad starve? This is where creativity comes in.

Evolution is commonly referred to as survival of the fittest. But it's really not. Evolution is survival of the most well adapted to the situation. While that works less well as a tag line, it describes the situation far more accurately. Change is constant in the outside world. An animal who can't get along despite the change – moreover, an animal that cannot use change to its advantage – will likely not survive. As [Runco \(2014\)](#) noted, adaptability is a key component of many theories of creativity. Animals may not paint or dance, but they absolutely create and innovate.

Examples of Animal Creativity

Invasive predators such as the cane toad in Australia are spectacular examples of how creativity and innovation can serve to keep animals alive. A toad in an unfamiliar environment must be creative to fulfill its need for food. It must find something to eat which is both novel (i.e. has never been seen before, because this is a new environment), and appropriate (a sufficient source of sustenance). The stakes are never higher – the lack of use of a novel food source means starving because the toad does not recognize any of the bugs. An inability to find an appropriate food source means attempting to get nutrients from chewing on old shoes.

The cane toad, as it happened, was particularly good at finding new food sources – namely, anything it could fit in its mouth. The toad, originally brought in for pest control, has now become an overpopulated pest in Australia itself.

Although it may sound slightly silly, examples such as these play out all the time in the natural world. Has the forest that housed your tree nest burned down? Did a drought cause your watering hole to dry up? Time to innovate. An appropriately creative animal may enhance its ability to find food, remain healthy, or produce more offspring. For example, the dolphins of Shark Bay, Australia, have adopted a habit of covering their rostrums (the “snout”) with a soft sponge while foraging. These animals forage by stirring up the dirt and sediment from the ocean floor, and the sponges protect them from cuts and abrasions from, for example, coral. In the wild, an infection of a cut or abrasion can be deadly ([Krutzen et al., 2005](#)).

There are many other noted examples of creativity in the animal kingdom. Consider the bowerbirds of Australia, a species in which males build elaborate bowers and “dance” in front of them to court females. Bright, shiny objects are valued and males who decorate their bowers with them tend to be more successful in their courtship attempts ([Borgia, 1985](#)). There is extensive tool use in primates such as chimpanzees who have learned to probe termite hills with a stick for a meal, or capuchins who use rocks as hammer and anvil to break open hard shelled nuts. In some of these cases, younger group members have been known to identify the best innovators and tool users and spend more time observing them than other members of the group ([Ottoni et al., 2005](#)).

Specific examples of animal creativity abound. There is the case of the subordinate chimpanzee who learned to bang together trash can lids to frighten other members of the troop, and thus moved up in the hierarchy and gained access to mating opportunities ([Goodall and van Lawick, 1971](#)). There is also Imo, a Japanese Macaque who discovered water could be both used to remove sand from her food before eating it, and to separate rice from dirt ([Kawai, 1965](#)).

In all these cases, individuals of a species have innovated an object or behavior which has significantly improved either their ability to gain food or access to mates. Because these innovative individuals have survival and mating advantages, they tend to produce more offspring – which in turn share the increased innovative abilities of their parents. Although it is difficult to study, there are basic characteristics and abilities which animals do show which can be used as a proxy for judging innovative ability. [Kaufman and Kaufman \(2004\)](#) (see [Kaufman et al., 2011](#)) has proposed a three-level model of animal innovation.

At the first level, an animal which innovates must be at least a little neophilic (attracted to novelty). Most of the time in the animal world, neophobia is the default – if it's new, stay away! New things could be harmful and the risk is rarely worth it. However, the cane toad which never approaches the weird-looking new bug is certainly going to starve. The trait Openness to Experience has been generalized to this in animals – often called boldness. And, like humans, animals show consistent and distinct variation both between species and within individuals of the same species – this is often referred to as “individual differences,” as opposed to the human term “personality.” A second trait associated with increased creativity and which varies across individuals within a species is behavioral plasticity (Carter et al., 2012; Chamove et al., 1972; Dingemanse et al., 2005). Behavioral plasticity is the amount of change which can occur within a standard behavior repertoire. Individuals with higher behavioral plasticity are able to nest on the top of a telephone pole when the trees are gone or slurp the remaining liquid out of discarded water bottles when the watering hole dries up.

Second, although not necessarily required for creative activity, very often creative animals are good at observational learning. There are many examples of well-known animals who have developed new and creative techniques (often associated with foraging for food), which have promptly spread throughout a population by observation and become standard behaviors (Ottoni et al., 2005; Povinelli et al., 1996). A cane toad watching its cane toad friend eat a bug, will not have its ability to survive impacted by whether it pauses to watch what happens to its friend. However, seeing and being able to imitate the behavior if it produces a desirable outcome, will certainly be a big help.

Several other common creativity theories can also be helpful to tease out how animals can be creative. The 4P's – Person, Product, Process, and Press (Rhodes, 1962) – each have animal analogs. The creative product is perhaps the most obvious way to examine creativity – in the examples above, this might result in a beautifully elaborate bower or a tool which works particularly well to crack open nuts. Likewise, the press or environment in which the creativity occurs is extremely important, albeit in a very different way from how the creative press is discussed among humans, as the beginnings of this chapter allude to. Often, creativity is necessitated by the status of the environment – or rather something which changes in that status. Available resources become key – a bird which might have the potential to build a nest on a telephone pole instead of a tree is unable to use that creative ability without nest making material being readily available. Groupings of animals within animals (called conspecifics) can impact innovation rates, although the research has yet to show any clear trends on the specifics. Studies of groups of animals have shown significant variation in innovation with group size and composition, but additional variables make the case less clear than a simple increase or decrease.

It is difficult to examine the creative process in animals; it is difficult to even make conclusions about the intentionality about many of the acts described earlier. It may be hard for people describe how or why they create, but we are at least, able to ask questions – a luxury we do not have with animals. Even planning is difficult to measure in animals, and there is little consensus on the extent or which it occurs or how that might be determined (Clayton et al., 2008; Correia et al., 2007; Suddendorf and Corballis, 2008). In one example, in order to obtain a reward a crow needed a tool of a certain length. However, that tool could only be obtained by using a second tool, which itself could only be obtained by using a third tool. And so forth. At least one member of the species has been reported to have been successful at the task and to have accomplished it in a purposeful manner. In other words, it obtained the tools in the correct order with little hesitation, as opposed landing on the correct pattern in which the tools needed to be used by random trial and error. Although this does appear to be evidence for planning and innovative use of the tools, it provides only a small amount of insight into the animal's actual planning and cognitive abilities as the inherent problem of lack of expression of the thought process remains (Wimpenny et al., 2009).

Finally, the creative person can provide an interesting way to examine creativity in animals. Often the creative person is modeled based on the 4Cs. The 4 C model frames creativity as mini-c, little-c, Pro-C, and Big-C (Kaufman and Beghetto, 2009). Mini-c is creativity which is personal and meaningful to an individual. Most animals innovating for food, play, social position, reproductive success, or exploration are creative at the mini-c level. Their creativity is “personal” and meaningful only to them – for example, a tool used to obtain food or a pretty flower used to decorate a nest. But innovations which spread among populations via observational learning begin to show characteristics similar to what creativity researchers call Pro-c, or professional level creativity. Consider for this level the cane toad mentioned above who tries the new bug. In some cases, particular animals actually gain a reputation for innovative abilities, or groups of animals learn to watch the group members who are most proficient at particular tasks.

The male bowerbird mentioned above is a different type of creative “person”; one for whom often times innovation can be useful in the competition for mates – i.e. sexual selection. His creativity is little-c; it's meaningful to more than just himself because it effects the other males nearby and the females being courted (Borgia, 1985). The bowers which male birds of this species build are not just elaborate nests, but are garnished with all sorts of objects the birds search out. Female birds (and thus the males courting them) prefer shiny, colorful, and novel objects. In some species, there is even a favorite color. After the bower is decorated, the male stands outside it and dances to invite the female in. Whether the female chooses him and enters his bower to mate appears to be directly correlated to the quality of his bower. It's as if the male is advertising that he has strong genes and good foraging skills – he has plenty to eat so he has time to look for decorations, and he is crafty enough to be able to location preferred objects. It's vaguely reminiscent of a poet with enough time and ability to produce sonnets for a potential beau. It is harder to determine if there are Big-C “genius” creators; however, there are certainly animals whose creativity continues to be remembered after their death, such as the African Grey parrot Alex who pioneered research in avian intelligence and showed us parrots had complex cognitive skills, could use language in purposeful ways, and were able to develop basic numerical skills (Pepperberg, 2012).

Lastly, and perhaps most intriguingly, some animals have enough cognitive abilities that they can be trained to innovate. “Innovate” or “Do something new” is a common behavior trained by zoos, aquariums, and training hobbyists in which animals can be asked to do an original behavior (Pryor et al., 1969). This can be as basic as the animal touching its nose to a ball and then to the

couch (a different object), or can, in some cases, result in triple back flips. Similar to how creativity can be measured using the Torrance Tests of Creative Thinking, it seems that the abilities of animals who know how to innovate in this situation can be measured by examining the fluency (number of behaviors an animal is capable of innovating), flexibility (whether the animal touches it's nose to different objects or shows more categorical variety), elaboration and originality (Kaufman and Kaufman, 2019). Many people are surprised by the creativity which animals can display here, as alluded to earlier, animals aren't something which might automatically come to mind about creativity. However, not only is it an excellent way of demonstrating those creative abilities, it is something that many pets and their owners do together for enrichment and to build relationships (Pryor, 1999).

Conclusion

Creativity in animals, much like creativity in humans, manifests itself in many different ways. Your dog might paint you a picture, but most likely he did it by walking through paint and then across canvas; not intentionally creating art. Nevertheless, your dog (and other animals) can be creative. These abilities may not serve to express emotion, communicate, or even consciously create new ideas as is typical of creativity in humans. However, whether through helping to adapt and avoid threats, find mates, or obtain food, they are vital to the survival of both individuals and entire species as environments and conditions change. From seeking out novelty or picking up new behaviors by observing peers to tool use or innovating in response to encouragement to actively problem solving and discovering new solutions, animal creativity can be small steps or giant leaps. Given the inherent difficulty of studying the topic, there is an impressive breadth and range of information available.

Glossary

Bauhaus ('House of building' in German) Name of an avant garde design, crafts and fine arts school, founded in Germany in 1919 by Walter Gropius. Until its closure in 1933 the school operated in Weimar, then Dessau and finally in Berlin, and had a profound impact on modern architecture, design and art

Beaux Arts Short for Ecole Supérieure des Beaux-Arts ('Higher school of fine arts' in French). The school was founded in Paris in 1648 and became independent in 1863. Beaux Arts schools were established throughout France, the rest of Europe, and later also America. They keyed on classical arts – Greek and Roman architecture, and studying and imitating the Great Masters and the classical orders

CAD/CAAD Computer Aided Design/Computer Aided Architectural Design. Computational tools that support designing with various kinds of software

Deconstructivist architecture A movement within postmodern architecture as of the late 1980s. It is characterized by fragmentation, manipulation of a structure's surface or skin, non-rectilinear shapes that serve to distort and dislocate some of the elements of architecture, such as structure and envelope. The theoretical underpinnings of deconstructivism were largely influenced by the philosophy of Jacques Derrida

Performatism A contemporary interpretation of performance in architecture, embedded in digital design, which aims to incorporate functionalist and image-based approaches to form making and conception

Postmodern architecture A movement and style within the postmodern culture that flourished in the 1970s and 1980s. It came into being largely in reaction against the starkness and uncompromising modernism of the International Style. Postmodern architecture is characterized by the combination of modern forms and materials with a highly conscious use of motifs and conventions from earlier periods including decoration, which was not accepted by the Modern Movement

Self/unselfconscious design Terms coined by Christopher Alexander. A selfconscious process occurs in a culture undergoing rapid changes that bring about random designed forms because designers are unable to respond to change systematically. Unselfconscious design occurs in a stable culture where occasional and slow changes cause only minor adjustments to robust, failsafe designed forms

Starchitect A star architect, who produces exclusive, so called 'signature buildings'

Vkhutemas (Acronym for 'Higher Art and Technical Studios' in Russian) Name of an avant garde art and technical school founded in 1920 in Moscow. It was dissolved in 1930 but was nonetheless responsible for one of the great revolutions in the history of art (constructivism)

Introduction

The history of designing buildings goes back several millennia. It is reasonable to assume that for a long time, huts, and later buildings, mostly of modest size, were made to respond to basic needs of shelter. However, social life, which had taken place primarily in the open, eventually also required accommodation in buildings as well. The first known building of a monumental size that is believed to have been the brainchild of an appointed architect is the Pyramid of Djoser in Egypt, designed by Imhotep between

2630 and 2611 BCE. Until the modern era, the history of architecture is told through mostly large-scale buildings with symbolic significance erected to house religious, government, cultural and social functions. The rulers who commissioned them also had palaces designed and built for themselves, to serve as status symbols as much as living quarters. In modern times other building types emerged that acquired architectural prestige (diverse additional cultural centers, commercial edifices, transportation hubs, educational institutions, and more). Residential buildings, other than houses for the very rich, were not considered worthy of architectural attention until rather late in the modern era.

Outstanding buildings do not spring into being by chance, as arbitrary triumphs of creative architects. Exceptional buildings embody ideas that had ripened within a culture or micro-culture and were translated into built form; in return, exceptional works of architecture often extend such ideas and promote further development of architectural theory. Thus, the history of architecture is largely a history of ideas; both general ones, which define historic styles, and individual ones that are responsible for outstanding buildings.

The two major aspects that guide the design of any building are function and form. Every building must serve the purpose for which it is being built, and it must have a physical form, which impacts upon both its users and those who perceive it from the outside as part of the environment. The evaluation of form and function is well aligned with the two most prominent measures of creativity: originality and practicality. In the behavioral sciences creativity is often measured as the sum of originality (novelty) and practicality (usefulness) of the outcome of a design undertaking. Although design of any kind is considered to be a creative activity, there are of course designs which are more creative than others, and it is these that are most interesting for this chapter. The entry will touch upon ideas in architecture, including the latest developments which are largely contingent on digital design technology. It ends with a section on architectural education which is greatly concerned with questions relating to ideas, form, function, and creativity.

Leading Ideas: Self-conscious Architectural Design

In 'Notes on the synthesis of form' Christopher Alexander, a leading design theorist in the 1960s and throughout the 1980s, distinguished between 'self-conscious design' (Alexander's original term), as practiced in the modern era by professional designers, and 'unself-conscious design', which was practiced by people who conceived buildings and other needed structures mainly before design became a formal professional activity in its own right. Unself-conscious design is responsible, well into the modern era, for what is referred to as traditional, vernacular or indigenous architecture, and is highly localized.

In 'The appearance of the form' John Habraken recounted how, in the twentieth century, a house was built for a priest in a small Dutch village. The carpenter who was charged with constructing it received the following instruction: "... the priest needed, unlike other folk, a room to study and receive visitors." This was all the information he needed; as for the rest, the carpenter had a very precise mental model of a house in that community, to which he merely had to add the extra room. The mental model addresses the 'style' of the building as well as all other design issues: the size, the room layout, building materials, and so on. In vernacular architecture buildings of the same type resemble each other; examples of the past are followed, and there is no drive to change anything unless it is absolutely necessary. The beauty of such architecture comes from its perfect adaptation to its surroundings and its function, as was cogently shown by Bernard Rudofsky in the MoMA exhibition and catalog 'Architecture without architects.'

In addition to the general cultural context in which it is embedded, more recent self-conscious design must also be understood in light of a narrower micro-culture to which a designer subscribes. Tradition is no longer enough of a moderating factor, and several approaches or design styles may be concurrently acceptable. Designers seek to belong to professional communities and to that end they subscribe to a micro-culture that best accommodates their values, beliefs and taste. This is a dynamic state, of course: cultures and micro-cultures do not stand still, nor necessarily do one's affiliations. Both traditional cultures and contemporary micro-cultures constrain design in terms of shapes, forms, patterns and their combinations. There are explicit and implicit rules that designers are expected to follow regarding the spatial world within which they play out their designs. 'Playing by the rules' is in fact one's ticket to membership in a particular micro culture, or design style. However, the most creative architects are known for their breakthroughs in which the rules are, at least, extended.

Striving for Novelty and Leading Ideas

Contemporary design is highly self-conscious. Architects strive to innovate within the culture or micro-culture to which they belong. To be considered creative architects have to try to push the boundaries of what is acceptable. In other words, they try to distance themselves from the typical in favor of a new and surprising design solution. More often than not, novelty rests on a 'leading idea' which drives the design. A leading idea in architectural design may be related to any one of different aspects of a building: spatial organization, building performance, the forms used to enclose spaces, façade composition, building materials, structural system, and so on.

Self-consciousness in design and the leading ideas that epitomize it are not restricted to contemporary times, of course. The Italian Renaissance architect Filippo Brunelleschi earned his fame mostly by devising a way to build the largest dome of his time, that of the Duomo of Florence, Santa Maria del Fiore. His creative contribution was the structural system of the dome. The contemporary architect Santiago Calatrava also built his reputation on the ingenuity of his structures, many of them bridges. In both cases the structural solutions are responsible for the striking architectural quality of the ensuing buildings. In contrast the

Swiss architect Le Corbusier, considered one of the greatest architects of the twentieth century, designed the residential building *Unité d'Habitation* in Marseille, France (1955), where the innovative feature was the spatial organization of the building. In this twelve-story building, which includes commercial and community facilities along an inner 'street' at mid-height, corridors run every third floor, leading to two-level apartments that span, on one of the levels, the entire width of the building. A very well known example of creative architecture due to novel building forms is the Guggenheim Museum in Bilbao, Spain, by Frank Gehry, completed in 1997, which, like other Gehry buildings, is composed of bold large curvilinear forms. Somewhat less known is the fact that the building also boasts an unusual application of a cladding material – sheets of titanium. A building that owes its fame entirely to the novel building material chosen for its enclosure is the Beinecke Rare Book Library at Yale University, designed in 1963 by Gordon Bunshaft of the firm of Skidmore, Owings, and Merrill. All exterior walls of the building are made of translucent marble, which transmits subdued lighting and provides much needed protection from direct light which would have harmed the rare manuscripts the building houses.

What the above examples have in common is the fact that all of them offered new solutions to at least one major architectural aspect. These architects did not follow precedents and succeeded in making a significant breakthrough by offering an entirely new way of treating that particular aspect. In terms of problem solving, it may be claimed that the novelty of the architectural solutions in these cases stemmed from a conscious breach of the habitual problem space (design space, in this case) in which the architects searched for a solution. Despite their novelty, however, even exceptional works of architecture continue to be embedded in their cultural circumstances and are identified by a style or movement they belong to (which, in extreme cases, they help create). However, contemporary digitally generated designs threaten to be independent of any context other than the technology used for their conception.

Styles and Paradigmatic Shifts

Styles and micro cultures are based on overarching ideas over which there is a consensus within the relevant communities at a given period. Such ideas are encompassed in theories, expressed in writing, often in the form of treatises. The earliest treatise still referred to today is by Vitruvius, a Roman architect and theorist who lived in 1st century BCE. His writings were rediscovered in the Renaissance and have had a lasting impact on architectural thinking and practice. Fil Hearn compiled the most important treatises throughout history and demonstrated the key role they played in shaping important works of architecture. Architectural styles are rooted in shared formal theories and the appearance of each style is accompanied by corresponding treatises.

The twentieth century saw the rise of three major styles: modernism, postmodernism, and deconstructivism. The modern movement was born at the turn of the nineteenth century. It strove to free buildings from formal historic compositional principles and excessive decoration, and to make them more suitable to the new lifestyles of a more egalitarian society that recognized everyone's right to live and work in improved built environments. With the social motivation, formal design principles were also widely accepted, including regularity rather than axial symmetry as an organizing principle, the breaking of large masses into smaller volumes that form three-dimensional compositions, and the removal of decoration in favor of volumetric composition as the main aesthetic appeal of a building. In the 1920s two new design education programs were launched, at the Bauhaus in Germany and the Vkhutemas in Moscow. In both schools the new ideas of modern architecture underpinned the curriculum, in contrast with the prevailing neo-classical approach that was the rule in Beaux Arts schools throughout Europe and North America (for further discussion on this topic please see below the section on Architectural Education).

Following an exhibition at the MoMA in New York in 1932 the ensuing style was dubbed 'International Style', a term advanced by Henry-Russell Hitchcock and Philip Johnson, who were the exhibition curators. Although the style was born in Europe and crossed the ocean to North America, today one of the largest concentrations of International Style buildings (some 4000) is to be found in Tel Aviv, Israel; the area in which they are concentrated is called White City as these buildings are predominantly white. The style was brought there by the many immigrants from Europe who arrived in Palestine in the 1930s and 1940s. In 2003 UNESCO proclaimed The White City of Tel Aviv a World Cultural Heritage site.

Postmodern architecture emerged as part of a wider cultural shift. It was mainly a stylistic tour de force, which rejected the austerity of modernism and embraced, once again, historicist and decorative connotations. Postmodernism was permissive rather than purist. For the first time the envelope of a building no longer had to express the volumes and spaces it enclosed and acquired an independent status of its own. Therefore, the modernist slogan 'form follows function' lost its currency during the postmodern era.

In the late 1980s a further stylistic development within the postmodern culture brought about deconstructive architecture, which was heavily influenced by the writings of the French philosopher Jacques Derrida who coined the term 'deconstruction'. The term refers to the close analysis and breaking up of texts into fragments that are not necessarily seen as co-existing harmoniously. In architecture, deconstructive work is characterized by fragmentation of building volumes to the point of tension among them, non-rectilinear shapes, often with sharp angles, and a dismissal of any formal commitment to building typology, which was important to modernist architects. In architecture deconstructivism is also akin to constructivism, a movement in art and architecture in Russia that was active from 1919 until 1934. The constructivists were part of the modern movement, but had a more radical and innovative approach to the treatment of shape and form.

Architects who pioneered these styles forged and developed the ideas that defined the styles, along with theorists and historians whose writings helped lay the foundation for the movements' theoretical underpinnings. Needless to say, there have always been voices that proclaimed other ideas, away from the mainstream. When postmodernism reigned, a smaller movement called

regionalism advanced different ideas: in opposition to the universalism of postmodernism they preached localism: respect for local culture, building traditions and so on. The deconstructionist era also saw, in parallel, a growing concern for the environment which was finally embodied in a movement for sustainable architecture, now also referred to as 'green architecture', which emphasizes the measurable performance of buildings (but not in opposition to spatial excellence), such as thermal comfort, daylight control, ventilation, energy consumption and even water recycling. At present no major style reigns in architecture (unless digital design is treated as a style; see 'The digital shift' below). This does not preclude new theories from influencing both practice and discourse about architecture. An example is the books by the architect Rem Koolhaas that have had more impact than the buildings he designed.

The Form-Function Dichotomy and Beyond

The dictum 'form follows function' is attributed to Louis Sullivan, a prominent American architect who was active when steel first became a primary building material late in the nineteenth century, used for the construction of building frames. Steel frames, along with the introduction of the elevator, made it possible to build taller buildings and Sullivan is known as a pioneer of skyscrapers design. This building type, completely new at the time, with the new design issues it brought with it, emphasized a renewed interest in functional aspects of architectural design. The turn of the century was a time in which many social and technological changes took place that encouraged a willingness to break away from conventions that had dominated in architectural design until that time. The new attitude was the background to the growth of the modern movement which, not surprisingly, endorsed 'form follows function' to the point of turning it into a slogan. Form and function were always conceived as two complementary but dichotomous parameters that define architecture. This is not to say that form or function are, or can be, mutually exclusive: both are musts in architecture.

During the 1960s a concentrated effort was made to introduce systematic, scientifically-based design methods into architecture. A number of international conferences related to methods were held, most of them in the UK, as part of what came to be known as the 'design methods movement'. Many of the methods in question were adapted from engineering and management, and their goal was to optimize design outcomes by ensuring that all relevant issues would be addressed properly. Two decades later it became clear that despite the efforts invested in design methods, they had failed to have an impact on either practice or education. There was more than one reason for this failure. First, the methods were very laborious and technical, and architects felt that they crippled their creative initiatives. Second, high hopes for automated processes in which computers would play a decisive role were premature and had left designers disappointed: computational technologies were far from capable of delivering the desired results. Third, and possibly the most important reason for the failure of 'methods' was the fact that with the advent of postmodernism, satisfying functional design requirements had lost its priority in favor of articulating form, or more specifically, the independent design of a building's envelope, into which spaces were fitted that accommodated the building's program. Exciting facades became so important that Robert Venturi and Denise Scott Brown, prominent architects and contributors to postmodern architectural discourse, wrote 'Learning from Las Vegas,' in which they talked about the acceptability of even the most simplistic box-like buildings, provided well-designed façades were attached to them like a billboard or very large advertisement. The consequences of this theory are discernible today in places like Times Square in Manhattan.

Today the term 'performance' has replaced function in discourse. The change of term signifies commitment to a higher-level scrutiny of building and environmental requirements, which is made possible with state of the art computational tools.

The Digital Shift

Computers have permeated design as they have pervaded almost every other area of life. The use of computers in design goes back to the 1960s, notably with the landmark system Sketchpad developed by Ivan Sutherland at MIT. By the 1980s CAD (Computer Aided Design) and CAAD (Computer Aided Architectural Design) became established research fields, taught in schools of architecture, and making their way into practice. Early computational tools were seen as supporting design in several ways, from drafting and the creation of fast and lively renderings, to flexible instantiations of designed objects through parametric control over design constraints. Specific programs were written for various building performance aspects, e.g., the determination of window sizes and shading requirements for best climatic performance.

Today's advanced digital design systems have generative capabilities and they are able to create non-Euclidean geometric spaces and transform them in the blink of an eye. Frei Otto designed the roof of the Olympic stadium built for the Munich games in 1972. The structure, considered very innovative for its time, consisted of large sweeping curvilinear canopies. During the design process Otto had to model the forms he was designing manually with elastic fabrics (allegedly he used ladies' stockings), as there was no way to represent their geometry accurately otherwise. Today structures like this are easy to model digitally. Moreover, up to a certain size complex forms can be manufactured with no need for any intermediary representation other than the digital model, which is fed into a CAM (Computer Aided Manufacturing) system. CAD-CAM systems are ubiquitous at high-end industries such as airplane and car production plants.

One of the immediate impacts that these new capabilities have on architecture is the ability to break away from the straight line in favor of an 'emancipated' world of rounded and curvilinear forms. This includes many varieties of spatial expression, some of which are sometimes referred to as "biomorphic." The term suggests a trend to emulate natural forms that, at different scales,

are by and large composed of non-Euclidian, curvilinear shapes and forms. This world of forms had been lost to architecture until now because it was not possible to represent and specify them properly, as in the case of the Munich Stadium. Now that this has become possible, and it is no longer excessively expensive to manufacture irregular building components, architects are at liberty to explore a whole new array of spatial forms, and a growing number of them, especially young architects and students of architecture, are happy to immerse themselves in this new and challenging universe.

Digital design is largely preoccupied with form, but it also advances the designer's ability to model and therefore predict and control the building's performance. Alternative values and tradeoffs can be tried out quickly and inexpensively in order to arrive at an optimal or balanced performance. The centrality of the issue of performance has led to a branch of digital design known as 'performatism'. Performatists stress the need to advance digital design not only in terms of forms and their production, but also in terms of the way they respond to needs, both needs of their own technical systems ('clever buildings') and the needs of the people who inhabit and use them.

The options that digital design opens up are vast and potentially revolutionary. At present we see collaborations between architects and other designers, engineers, materials scientists and computer science specialists, who endeavor to push the boundaries of architecture. Using tools of artificial intelligence, robotics, 3D printing and biological processes, completely new concepts of architectural space are created. An example is the work of Neri Oxman and her associates at MIT's Media Lab. The Silk Pavilion they created in 2013 was a dome the skeleton of which was made of aluminum scaffolding onto which an initial lattice of silk threads was strung by a robot. Then live silkworms were placed on this lattice and over a period of several weeks the worms span their own silk threads until the entire dome became almost entirely opaque. Works of this nature give us a glimpse of future possibilities which, to a large extent, are still difficult to imagine.

How will people relate to complex forms of such different geometries? How will structures relate to one another? Today they are treated rather as discrete objects, whereas there is generally a preference for thinking of buildings within contexts, primarily urban contexts, where continuity and coherence of a broader urban fabric are sought and open urban space is planned to complement buildings with equal heed and prudence. What would such an open space be like if the buildings that abut it were all composed of forms that were convex and curved onto themselves and usually turned a concave and possibly alienating face to what surrounds them? How will people inhabit and furnish curvilinear spaces should they be severely constrained in size, in contrast to vast spaces in current tour de force examples? For example, the Dalian International Conference Center in China designed by Wolf Prix of Coop Himmelb(l)au and inaugurated in 2012, or Zaha Hadid's Dongdaemun Design Plaza in Seoul, completed in 2014. Both these landmark buildings require vast open space around them because they cannot be integrated into a continuous urban fabric.

Most importantly, the new technologies pose questions regarding the very act of design, and the role of the architect. The new digital systems are imbued with intelligence that allows the architect to try different values for the same design parameters and obtain results that often surprise the designer who may receive unexpected outcomes. The future architect will most probably continue to make the decisions, but what decisions? Is he or she to choose from among proposals obtained digitally, adjusting the input so as to come closer to satisfying constraints or requirements? Who will determine the constraints and requirements, or the goals? In other words, conventional artificial intelligence as it is known today will no longer suffice; it may become necessary to talk about a higher digital intelligence, and digital creativity, at least as far as design is concerned. Such intelligence and creativity will have to be pitted against the architect's creativity and intelligence. The old question regarding the nature of the partnership between the designer and the computer in the design process has never been as acute as it is today. It is hard to predict what architecture and architectural practice will be like a few decades from now, but it is certain that the digital shift will have a profound and irreversible impact on built form and its production as they have been known and practiced until the present.

Starchitects and Other Practitioners

Although architectural design, and design in general, are creative activities by definition, not all works of architecture are equally creative, nor are all architects uniform in their creativity. In a paper published in 1962 Donald MacKinnon presented a study of personality correlates of American architects, in which he found that there were significant personality differences between more and less creative architects. Creativity correlated positively with higher levels of affective intelligence, openness to experience, freedom from petty restraints and impoverishing inhibitions, aesthetic sensitivity, cognitive flexibility, independence in thought and action, high level of energy, unquestioning commitment to creative endeavor and unceasing striving for creative solutions to ever more difficult architectural problems.

In a book published in 1998, the sociologist Garry Stevens looked at architectural practice and found it necessary to distinguish between architecture as a field and architecture as a profession. The profession is the more mundane of the two; it represents the business of designing buildings for clients to fulfill defined purposes. In their capacity of architects working in the profession, architects provide design services to clients, be they owners, users, or representatives of public or private organizations. It is a business-oriented activity in which architects try to excel, while being highly client-minded and constrained by the client's directives. Expertise is much valued in the architectural profession, and there are firms that develop special expertise in a particular building type, e.g., hospitals.

The architectural field transcends ordinary practice. It is more concerned with innovation and with a cultural discourse through writings and built form. Architects who operate in the field of architecture are privileged; they see themselves, and others regard them, as practicing at a higher level than other professional architects. They are status oriented and instead of being client-minded

they are eminence-minded. They hope to produce landmarks, rather than buildings that ‘just’ serve their users well. Clients turn to architects of this kind when they are interested in a product that would serve as a status symbol, and are willing to compromise some of their control over the building program and design decisions. They are also willing to pay higher fees, in addition to higher construction costs.

Stevens calls the architects in this group ‘the favored circle’. Those at the top of the list are known to us as ‘starchitects’: they become cultural heroes, even celebrities, and their iconic buildings – ‘signature architecture’ – are included in lists of attractions to be visited by tourists. A well-known case in point is the Guggenheim Museum in Bilbao, Spain, completed in 1997, by Frank Gehry. The building is said to have done wonders for Bilbao, then an industrial city with a decaying economy, by bringing in an average of close to one million tourists each year (about eight times the number before the building was built). The project costs were overwhelming (over 200 million Dollars), but the city gained hundreds of new jobs, hundreds of thousands of overnight stays annually, along with other business that tourism generates.

Starchitects are definitely among the most creative of architects. Their creativity rests primarily on exceptional originality, whereas in terms of practicality they do not necessarily achieve better results than other good architects. In fact, sometimes there are serious functional flaws in their buildings. But striking, original forms are received with so much admiration by the public at large that functional flaws are often met with forgiveness. In this respect, architecture occupies possibly a unique position as far as the balance of novelty and effectiveness in creativity is concerned, and in that it is closer to the visual arts. For example, the Sydney Opera House by Jørn Utzon, completed in 1973, cannot carry out all the functions that those who commissioned and paid for it envisaged (the staging of large-scale opera productions). However, because it looks beautiful this flaw is forgiven. By contrast, it is impossible to imagine public acclaim being given to, let us say, a bridge that was built at great cost to carry traffic across a river but turned out to be useless because of engineering flaws, even though it looked beautiful. Thus, to some extent architecture is less bound by the insistence on function as part and parcel of the definition of creativity in the literature. (see also the chapter on: *Definitions* within the Encyclopedia that novelty must be effective).

Architectural Education

The history of university-level professional education in architecture is relatively short. Before World War I, the great majority of schools of architecture in the western world were modeled after the French *Ecole Supérieure des Beaux Arts*, which was founded in the seventeenth century by the *Académie Royale d'Architecture*. Its main purpose was to serve the needs of French aristocracy. Throughout its long existence, Beaux Arts education promoted the value of historical precedents and the primacy of the great classical traditions. The Beaux Arts educational system was extremely influential and many a school in Europe and beyond followed its tradition and were hence identified as Beaux Arts schools (to distinguish them from schools of other ‘denominations’). Leading nineteenth century American architects went to Paris to study at the *Ecole des Beaux Arts*. A Beaux Arts diploma was in good currency in the USA well into the twentieth century. Creativity was not a prime goal of standard Beaux Arts education (with exceptions in the last years of its existence); the fostering of creativity and innovation had to await a later major cultural shift. European Beaux Arts schools of architecture were widespread until the 1960s, alongside other types of schools, notably the ‘Polytechnic’ institutes and schools that reflected the ideology of the Modern Movement. In France the Beaux Arts system was abandoned only after the events of 1968.

An alternative model of architectural education was launched in the 1920s in Europe in two avant-garde institutions, the Bauhaus in Germany and the Vkhutemas in Russia. In both institutions architecture was a unit alongside other units devoted to the arts and to crafts. The foundation of the new schools resulted from novel cultural attitudes and from reforms in education prevalent in contemporary arts, design, and architecture in the aftermaths of World War I and the Russian Revolution. These reforms, which rejected classicism, were strongly motivated by a social and political agenda and by a wish to empower the arts, the crafts and design through the use of industrial and technological advances. Experimentation and creative initiative were central to the educational philosophy of the Bauhaus and the Vkhutemas, as opposed to the conservative approach of the academies, embodied in Beaux Arts education. Although the avant-garde Bauhaus and Vkhutemas were shut down prematurely due to the political circumstances of the 1930s in Europe, they exerted a lasting influence on architecture and architectural (and design) education. In fact, the term Bauhaus has become an emblem of the modern movement in design and architecture, still in wide use today (and often erroneously replacing International Style).

The second half of the twentieth century has seen a phenomenal growth in higher education, for which the university has become the prime vehicle. Many new universities were founded around the globe. The great majority of schools of architecture, whose number has surged proportionally, operate today as academic departments within universities, sometimes independently but often in partnership with other departments (e.g., planning, construction, environmental studies, engineering, or art). Despite the many differences among schools of architecture and their institutional contexts, almost all of them share similar goals and the programs they offer are based on training principles that were, to a significant extent, inherited from the Beaux Arts and the Bauhaus-Vkhutemas traditions. The omnipresent design studio, central to the curriculum of every school of architecture, is a direct descendant of the Beaux Arts’ atelier. Striving for originality and innovation and the legitimization of exploration and search by trial and error have been handed down from the Bauhaus and Vkhutemas, and today creativity is the single most valued capacity students are expected to demonstrate. A similar development is now being seen in technological design education, as well as in other areas such as entrepreneurship education, where creativity is receiving much greater attention as a goal of teaching (as against for instance,

mastery of techniques or tools). Accordingly, the role of the studio teacher has evolved: from studio 'master' (or 'mistress'; until a few decades ago, architecture was a predominantly masculine occupation and most teachers were men) to what is sometimes referred to as 'coach'. Needless to say, new curricular components have been and continue to be added to professional education to catch up with technological and scientific developments, notably computational options and new building materials, as well as dynamic social and environmental sensitivities and awareness.

Introduction

I have spent most of the last 20 years moving back and forth between two areas: As a practitioner I have developed AI software and used it to support decision makers. As a scholar I have been studying the human mind, focusing particularly on the highest level of expertise and on elusive phenomena, such as intuition and creativity. Naturally, I got interested whether AI can perform on par with the human mind, supersede it, and whether there is anything unique in the human mind that cannot possibly be achieved by AI as expressed through machines. Ultimately, my most important question always has been how to create a synergy between human mind and AI; in other words, I became interested in what is recently referred to as Augmented Intelligence.

Why is it useful or perhaps even necessary to have a chapter on AI in a creativity encyclopedia? The first, and perhaps, the most obvious reason is that many people today want to know whether we can ever expect AI Creativity (Amabile, 2019). Second, if there is a chance that AI can play a role in human creativity, it is worth exploring. The third reason, conceivably the least obvious one, and the most significant in my view, is that understanding AI (even in non-technical terms), can help creativity researchers understand human creativity better. The reason for this significance is that as we are trying to build AI, we must use what we know about the human mind, and in the process, we achieve greater clarity of the limitations of our understanding of the human mind. This is perhaps the most obvious in the case of creativity. For instance, we often intuitively classify an achievement as creative, and we do not think about explaining what makes it creative. However, if we compare such creative achievement with a similar or even superior achievement by AI, we do not necessarily want to label it as creative. This makes us think about what qualifies some achievement creative. In other words, if we want to put something into a machine, we need to put it into words, and in order to put something into words, we need to understand it. Therefore, my primary focus in this chapter is this third reason, although I will briefly address the other two as well.

The term artificial intelligence denotes both making intelligent machines as well as studying them. In line with the above argument, AI gurus, such as Herbert Simon, often noted that the field of AI includes studying the human mind. AI is loosely defined as machines that can accomplish tasks that humans would accomplish through thinking (through intelligence, as intelligence in AI is considered much broader than psychometric intelligence). It is interesting that the definition does not say anything about accomplishing such tasks the same manner as humans do; I will get back to this point below. To set the scene, I start with a brief overview of the history of AI.

A Brief History of AI

There are two distinct roots of AI, one is usually referred to as symbolic AI, the other connectionist AI. These two roots have come together, to a varying extent, in today's AI applications, but started as separate roots. Before the "AI-era" began, there was, however, one important work published where Alan Turing (1950), in his seminal paper, introduced the Turing test, machine learning, genetic algorithms, and reinforcement learning. In many ways we could say that we are still working our way through the challenges outlined by Turing.

The Symbolic Approach

According to the AI folklore, the history of AI began when Herbert Simon returned to the Carnegie Institute of Technology (today Carnegie-Mellon University) after the New Year in January 1956 for his class on Mathematical Models in the Social Sciences and told

his students: “Over the Christmas holiday, AI Newell and I invented a thinking machine”. One of the students in the class was Edward Feigenbaum (1992: 3), who recounts this sentence as the reason to become Simon’s PhD student, and who was later to become the father of knowledge-based expert systems, one of the important areas of AI. During the same year, a conference was organized in the Dartmouth College, at which John McCarthy coined the term “Artificial Intelligence”.

The Logic Theorist was the “thinking machine” that Newell and Simon created together with Cliff Shaw from RAND Co., the company that gave them access to a computer (a power-hungry IBM 701 with less than 20 kb memory, using unreliable vacuum tubes, costing millions of dollars). The Logic Theorist was supposed to try to find solutions to complex problems, such as proving mathematical theorems, when it is not even known if there is a solution. The Logic Theory Machine project was followed by the more ambitious General Problem Solver (GPS), which was supposed to extend this scope to any and all problem areas, such as deriving scientific rules from data or playing chess. This should have been achieved by following the steps of human problem solving, and replicate achieving the outcomes (i.e. solutions to the problems). The idea was that if we do this across a number of problem areas, we could develop AI that could apply the general principles of reasoning, and thus would not only work within a narrow well-defined scope, but across various domains. This type of AI is also referred to as “wide-AI” or, more recently, Artificial General Intelligence (AGI).

Moving to Berkeley, away from the direct influence of Simon and Newell, Feigenbaum got more and more interested in creating a machine of superb performance, possibly superior to human performance. Instead of focusing on the general principles of reasoning, he focused on the role of specialist knowledge at a high level of expertise. His dream was to build a super-intelligent machine. As he realized that the previous AI solutions were good at deductive but not so good at inductive reasoning, Feigenbaum was looking for a problem in which hypothesis formation could be captured by inducing internal models of external environments. Partnering with the Nobel Laureate Joshua Lederberg, he ended up with the problem of inducing topology of molecules based on their mass spectra. The DENDRAL project, as it was called, lasted for many years, involved further subject area experts, but at the end, the program was performing at the level of the top experts. This was the first knowledge-based expert system. A system being “knowledge-based” refers to the internal model called “knowledge representation” which was stored in the form of a “knowledge base”, while the term “expert system” signified that expert knowledge was being modeled.

Both, the GPS (and the previous Logic Theorist) and the DENDRAL relied on a process called “knowledge acquisition”, through which human thinking about a problem was captured in the form of logical “if... then” rules. As such rules can be implemented as symbol manipulations, such systems became known as symbolic logic, or symbolic AI. There was, however, a great divide between the two directions in symbolic AI. One direction was to attempt building a domain-independent AGI, through capturing the generic process of problem solving. The other direction was to build expert systems (or knowledge-based systems or knowledge-based expert systems) in a well-defined narrow area by modeling subject-specific knowledge of experts. Knowledge bases typically comprised a few hundred to a few thousand “if... then” rules, they rarely reached the range of tens of thousands (and this was inevitably only possible by involving multiple experts).

Knowledge-based expert systems dominated the AI landscape until the mid-1980s, producing a large number of very successful implementations in a wide range of areas from science through manufacturing to medical treatments. At the same time, the AGI approach did not produce any implementations that would successfully work across multiple domains, but some implementations were successful in narrow domains.

The Connectionist Approach

While the symbolic approach to AI was dominating the early days of AI, the connectionist approach has been developed earlier. The first Artificial Neural Network (ANN) implementation was done by Marvin Minsky and Dean Edmonds, as part of their graduate work at Princeton in 1951. The purpose of these ANNs was to demonstrate that any mathematical function could be calculated by a suitable network of artificial neurons; therefore, this was not what would today be regarded as AI, but might be regarded as “pre-AI”.

ANN, however, became somewhat dormant until the mid-1980’s, when it had a big comeback. There were several reasons for this comeback. The AGI approach did not produce any solutions that would work across domains, expert systems were confined to their narrow areas and took extremely long times to develop (often becoming obsolete once the problem was solved), and computers became sufficiently fast to cope with ANN of a useful size. ANN are today perhaps the most heard of forms of AI, in fact, ANN seems to have monopolized much of the AI area, including the concept of machine learning. Therefore here I provide a very much simplified but in-principle correct description of what ANN are and how they work.

Any ANN consists of three layers of artificial neurons. There is an input layer, that receives some kind of signal (stimulus)—a stimulus can be more or less anything we can convert into an electronic format. Then there is a hidden layer, which performs some sort of black-box operation between the input and the output. Finally, the output layer produces a response to the stimulus received by the input layer. Nowadays we often hear terms like “deep ANN” or “deep learning”, which sound mystical and exciting; in fact, these simply mean that there is more than one layer of artificial neurons in the hidden layer. Computationally this makes a great deal of difference, but logically the concepts are simple. The artificial neurons are connected to each other across the layers, like synapses in the human brain, hence the term connectionist approach. Each connection has an initial weight, so as the stimulus “ignites” the system, the signal propagates toward the output neurons resulting in a response. The response is compared to what was expected, the weights are adjusted, and the process is repeated iteratively. As it is easy to process a large number of learning samples

(stimulus and the desired response), the ANN can relatively quickly adjust to producing the desired response. In other words, ANN learns from a large number of learning samples how to reproduce the statistical frequency of those learning samples.

So the logic is simple, but then comes a twist. As the artificial neurons were modeled after the biological neurons, more precisely after our knowledge of the neurons at the time, the ANN, supposedly, resembles the human brain. Therefore, so the argument goes, if we put together a sufficiently large ANN, it should think. Furthermore, as the digital neurons are faster than the biological ones, these machines should be, following this line of thought, smarter than humans are. Although this logic may appear sound at the first sight, it is heavily based on assumptions and beliefs, and also seems quite unrealistic for the present times – at least to me. Let me unpack this assertion.

My first point is about the size of ANN. The human brain is taken to consist of about 100 billion neurons, with around 7000 connections on average, resulting in some 1000 trillion (10^{15}) synapses in total. The largest ANN I have seen consisted of a few dozen artificial neurons, although I know that there are some in the hundreds. It is not public knowledge how many neurons the most advanced ANNs, such as the one in DeepMind, comprise today but I would expect a few thousand. In these exceptionally advanced systems, an artificial neuron perhaps may have a few hundred connections. This means a few hundred thousand synapses in total, suggesting that ANN is only about 10 orders of magnitude short of the human brain's network. True, in the last 70 years ANN architects managed to achieve an increase of 4 orders of magnitude, so another 10 does not sound like science fiction. But it is surely reaching the level of complicatedness (rather than complexity, see later) which cannot be grasped by the architect anymore; the only way to analyze such huge AI is using AI. In other words, I am hesitant to believe it is only a matter of time until we produce functioning ANN of a similar size as that of the human brain.

My second point is about the structure of ANN. In such a network the connections always go forward, that is a neuron from any layer only connect to the ones from the next layer (in some networks there can be within-layer connections as well). We do not really know if there are any circular connections in our brains, but there may well be. Furthermore, I am not even sure that we should think in "layers" about the brain. In other words, while structurally ANN resembles the brain in being complicated, a closer look at the structure also reveals dissimilarities.

The third point concerns the functional aspect of ANN. The functioning of artificial neurons reflects what we knew about biological neurons around the mid-20th century—that neurons are either "firing" or not, resembling the digital computers. Today, it seems that at least a small subset of neurons (maybe only a few million?) displays a more complex behavior, more akin to analog computers. This means that functionally ANN is rather limited in comparison with the human brain.

If ANN architects managed to overcome all the difficulties of the previous three points, they could construct something like an artificial brain. Some enthusiasts emphasize that as the artificial neurons are faster than the biological ones, the artificial brain should be better, or at least faster, than the biological one. However, here we face another assumption barrier: that the brain, if structurally, dynamically, and functionally adequate, would produce the mind. It may be that many find this assumption plausible, but it is just a belief. However, what science knows so far is that the brain and the mind are somehow connected, and particular thinking processes can be associated with neural activities in particular areas of the brain. We do not really know whether the brain produces the mind, the mind produces the brain, they co-produce each other, or the brain and the mind are produced separately and linked. The typical computer science analogy for cognition is that the brain is the hardware and the mind is the software—although the software is running on the hardware, hardware has never produced software.

Finally, recent research also suggests that the brain is not the only part of our biological setup that participates in our cognitive system; our endocrine systems also seem to be part of it, and I would not be surprised if we found in the coming years that our whole body is, meaning that the mind is fully "embodied". In other words, if an artificial brain was produced, reasonably approximating the human brain in size, structure, and functioning, this does not imply that it will produce an artificial mind.

AI Paradigms

I have noted above two divides in AI. The first divide is between the symbolic and connectionist approaches, a divide which is technologically fundamental. There are further tools and implementations that belong in the AI landscape, such as fuzzy logic and genetic algorithms. I have not gone into the details of these here, as they do not offer different approaches to AI. Fuzzy logic is usually used in a connectionist way, in combination with ANN or on its own. Genetic algorithms are well aligned with ANN, and they could be used in symbolic AI as well—although I have only seen examples of this in computer games. The second divide is between artificial general intelligence (AGI), aimed at wide application area with less concern on current performance, and expert systems, aimed at high performance in a narrow area. In this section, I introduce a third divide, which is somewhat like an extreme version of the AGI versus expert system divide; these are the paradigms of AI: strong AI versus weak AI (referring to strong versus weak assumptions).

Strong AI means creating a thinking machine that equals humans in every cognitive aspect. According to the proponents of strong AI, these machines were not only expected to think, and deliver performance that is on par with human, they were also expected to think the same way as humans do. This kind of AI is expected to awaken to self-consciousness, and have intentions, emotions and sensitivity. In principle, there are two ways to achieve strong AI. The first way is to attain a complete understanding of the human mind and then the ability to replicate it artificially. Unfortunately, or luckily, depending on where you stand, we are nowhere near to being able to understand the human mind. If we take complexity theory seriously, we have to accept that we cannot ever achieve this, as no system can understand another system that is at least as complex as itself. The second way to achieving strong AI is to admit that the human mind cannot be fully understood, at least for now, but maintain the belief that it is possible to create

an artificial brain that will then produce an artificial mind, which is like the human mind as we know it. Based on everything stated above, and on what most AI experts say, having a human-level and human-mode thinking machine cannot happen in the near future. However, there are a few enthusiasts, some of them the greatest minds of AI, such as [Simon \(1977: 6\)](#), who said:

"I believe that in our time computers will be able to perform any cognitive task that a person can perform. I believe that computers already can read, think, learn, create ..."

Those who subscribe to the weak AI paradigm, believe that we do not, at least currently, understand the human mind well enough to reproduce it. Perhaps even more importantly, they want to align their efforts with a purpose that sounds less grandiose, but is aimed at producing useful and meaningful results right now. So they want to build specialist applications, such as expert systems, that work well in a narrow predefined domain, and only performance is of interest, it does not matter if the machine achieves it in the same way as a human would. My personal beliefs are closer to this approach and, as a practitioner, it is certainly my preference to produce something that works right now. I always tell my students a metaphoric example: "When they wanted to go somewhere, our great-grandfathers called a carriage. Today we call a taxi. The taxi is not an artificial horse, it works on completely different principles, but can do the same job of taking us where we want to go, in a different way, perhaps even better (e.g. more conveniently and faster). In order to make the taxi, we did not need to understand everything about the biology (and perhaps even psychology?) of horses, we had to understand the internal combustion engine and the wheel. Of course, the taxi cannot substitute the horse in every task, for instance we cannot play polo on it. But it can take us where we want to go". Similarly, today we understand a lot more about computers than we understand about the human mind. And we can make useful tools using computers, using AI. AI is far better at many things than humans are, often these are things that humans do not find particularly interesting anyway – and it cannot do some things, at least for now, that humans find easy. Then, again, this is also true for a seeding machine or a coffee mill.

To be fair to those in the strong AI paradigm, they do produce things that work right now. The stories on the websites of DeepMind or Watson show a number of projects that are incredible, useful as well as meaningful, while others are interesting and funny. Perhaps it would also be fair to say that DeepMind and Watson transcend the strong-weak AI paradigmatic divide.

What AI Still Can't Do—and What It Does Well?

So how do we know that a computer is thinking? How do we know if it should be considered (artificially) intelligent? The first criterion is the Turing test ([1950](#)), which is still usually referred to as a qualifier. The essence of the Turing test is that if we interact with an entity and we cannot figure out whether we are talking to a person or to a machine, and it is in fact a machine, that machine should qualify as intelligent. On first sight this sounds convincing—if the machine is not really thinking, we should be able to catch it out. So has any machine (computer program) passed the Turing test so far? Yes, quite a few did, from ELIZA through a number of chatbots, to Eugene Goostman, the simulated 13-year-old Ukrainian boy, and an AI course moderator at MIT. Instead of getting into the details whether these instances of passing the test were legitimate, let me ask different questions. So what if a machine passed the Turing test? Would that really mean that it was thinking in the sense we attribute this verb to humans? No, I do not think so. The programs that passed the Turing test were designed with this purpose, not with the purpose to think.

Perhaps the most convincing argument against the Turing test comes from John [Searle \(1998: 11\)](#)—that became known as the "Chinese Room Argument". The essence of the argument is the following: assume that I do not speak Chinese, and I am in a room full of rule-books, receiving messages in the form of Chinese symbols and looking up responses to those messages in the rule-books. If the rule-books are good, those outside the room, receiving the responses, would believe that the person responding understands Chinese. And they would be wrong, I did not miraculously learn Chinese. The same way, passing the Turing test does not prove that the computer thinks, only that the program is good.

[Minsky \(2006\)](#) reposts to Searle by reversing the Chinese Room Argument, creating a hypothetical "zombie machine". The zombie machine is seemingly identical to the human and, if it injured a leg, it would complain about the pain (as it was programmed to do so). The response to the pain would be indistinguishable from a human with a pain in the leg. If this was done, could we claim that the zombie machine's leg does not hurt—that it does not feel? But the most brilliant part is the final turn: if we cannot distinguish the zombie machine from a human being, can we claim that the human being feels?

Of course, none of the above proves that the machine does not think, the arguments only falsify the validity of the evidence that it does. So, we are left to our beliefs as there are no conclusive proofs. Another important thing that we can learn from the above is that we do not have a way to directly measure knowledge or thinking, what we can do is make inferences from the performance. This is not a unique situation in the world of science, all the work done in quantum physics is similar, elementary particles cannot be put under a microscope and it is impossible to measure their weight or speed or similar. What physicists do instead is to observe interactions of elementary particles and infer their characteristics. Physicists come up with models, speculatively, conduct experiments in which they measure some effects, and from these they infer various characteristics and check whether these are consistent with their speculative models. That is probably the reason that there is no single model accepted by all quantum physicists. Many different models can be consistent with the same results, depending on our inferences.

So, instead of trying to prove that AI can or cannot think, it is perhaps more useful to look at the performance of AI and the related claims. In 1957 Herbert Simon announced that the chess world champion will be an AI machine within 10 years. However, it was only in 1997, four times longer than Simon predicted, that Deep Blue defeated Garry Kasparov, who is possibly the best (human) chess player of all times. Since then we had AlphaGo defeating the world champion Lee Sedol as well as all the other Go grandmasters, AlphaGo Zero winning consistently against AlphaGo, and AlphaZero beating not only the previous two but also the best computers in chess and shogi. Let me unpack how AI achieved this extraordinary performance and what it means.

There are four different “pure” ways for AI to become “smart”. The first is to hardcode a program specific to the chosen performance area. These are “purpose-built programs”, such as Deep Blue which was programmed to play chess. The second way could be termed “process capturing”; it characterizes the previously mentioned Logic Theorist and the subsequent General Problem Solver. The essence of this approach is to record the steps of problem solving by human experts using the “thinking aloud” technique. The third approach is “knowledge representation”, which is primarily used by knowledge-based expert systems. Knowledge engineers build knowledge bases from knowledge acquired from domain experts, while the processes of how these knowledge bases are used, are programmed. Finally, the fourth approach, “machine learning”, is to let AI learn with or without humans interfering with the process. This approach is predominantly associated with ANN, but all forms of machine learning belong here, including those in the symbolic AI realm (e.g. [Quinlan, 1986](#)). Of course, apart from these pure approaches there are also various mixed approaches within and across these categories.

Each of the above approaches has at least one of the following two characteristics: they require *explicit knowledge* or they follow a *reinforcement learning process*. Both of these impose severe limitations on what we can expect AI to do. In fact, these limitations should be sufficient in themselves to convince most people that AI, as approached today, can never think and learn in the sense of human thinking and learning. This also suggests that AI Creativity, in the human mode, is impossible. This is explored at a greater depth in the next section; here I want to examine the broad implications of these two characteristics.

The first characteristic limits human knowledge to explicit knowledge. While it is widely known that humans also have, and use, tacit knowledge, [Polányi \(1966: 7\)](#) goes much further claiming that there is no knowledge without tacit knowledge:

“While tacit knowledge can be possessed by itself, explicit knowledge must rely on being tacitly understood and applied. Hence all knowledge is either tacit or rooted in tacit knowledge. A wholly explicit knowledge is unthinkable.”

Considering that much of what we know about knowledge today originates from Polányi, we must take seriously his assertion. AI that uses any form of knowledge representation, hardcoded, in the form of knowledge bases or as embedded problem solving steps, is limited to explicit knowledge. This explicit knowledge is always used in the process of formal logic, and even Simon, who was extremely optimistic about the prospects of AI, warned that formal logic is only one of the instruments of reasoning. Knowledge-based expert systems respond to this limitation by focusing on a narrow domain and fine-tuning the knowledge bases together with the domain experts, until it reflects their judgments. In the process, occasionally, something in the tacit knowledge of the experts becomes explicit, that is, something is spelled out that the experts already knew, only they did not know that they knew it. This rare event is called “knowledge discovery” and is often considered to be the most valuable aspect of the knowledge engineering process.

Limiting learning to reinforcement learning is at least as significant a departure from human learning as limiting knowledge to explicit knowledge. There was a period in the history of psychology, called behaviorist psychology, when reinforcement learning was considered to be the only way of learning. While it was therefore sensible for Turing to suggest reinforcement learning in 1950, psychology has come a long way since its “dark ages”, when it denied its own topic of research considering the mind a black box. At the heart of the reinforcement learning approach is the stimulus-response (S-R) model; the entity (human, animal, machine) receives a stimulus and provides a response. We reward the preferred response and/or punish the non-preferred ones. Sooner or later, the responses will align with our preferences, and this is considered learning. Of course, there are a few things that humans learn this way, for example a child will quickly learn not to touch a hot stove. However, we also learn from stories, get inspired, are talented for some things and not for others, commit to master-apprentice relationships, etc. Reinforcement learning covers only a tiny part of our learning.

Both of these issues, limiting knowledge to explicit knowledge and limiting learning to reinforcement learning, are captured in the concept of “common sense”, contrasted to specialist knowledge. As [Minsky \(1988\)](#) said, it seems to be easier to create AI that performs at an expert level in a narrow domain than to make a program which could play children’s games or bring in the newspaper from the front door to the breakfast table. According to Minsky, common sense is an immensely complex system of rules, and exceptions, practical ideas, dispositions and tendencies, balances and checks. It appears simple and natural as we have lost touch with how we learned them—and we know almost nothing about how common sense is acquired. Interestingly, most researchers from strong and weak AI paradigms agree that the missing link to creating a thinking machine, and by implication AI Creativity, is the model of common sense. The difference is that according to the strong AI community it is only a matter of time before a model of common sense is obtained, while according to the weak AI group it is impossible. There were several attempts to develop artificial common sense, among others the “CYC knowledge base” (by Cycorp), which is probably the largest knowledge base ever produced, comprising “millions of facts, beliefs, and other bits of knowledge” ([Feigenbaum, 1992: 17](#)). All these attempts have remained futile

so far and none showed any promising progress toward modeling common sense. Perhaps, it would be sensible to ask whether there is any meaningful concept of intelligence (human or artificial) at all without common sense.

The above is a sufficiently convincing argument that AI does not think or learn the way humans do. However, this does not necessarily mean that AI does not think or learn in ways that are different or only partially overlapping with the human ways. As I indicated previously, to deliver a particular performance, it is not necessary to do it as humans do – and we can see that AI can beat us in areas like the game of Go. All the success stories, however, are in relatively narrow domains. With rare exception, such as DeepMind and AlphaZero, this means one single problem area. DeepMind is usually represented as a wide-AI. However, it does not cover the whole spectrum of human problem solving, it only plays various computer games designed for Atari computers (an early PC of the 1980's), while AlphaZero plays Go, chess and shogi. Although it is a significant step forward that DeepMind (which is also at the core of AlphaZero) can cover more than one domain in a single system, playing the different games is very far from covering a full range of human problem solving, such as leading an organization, writing a poem, nursing a patient, or enjoying a football game (as a fan). In short, there is convincing evidence that artificially reproducing thinking and learning (and by implication creativity) in a human mode, is impossible, at least for the time being. In the next section, I explore how AI does in the area of creativity, which is traditionally considered a particularly human endeavor.

Creativity and AI?

Can AI be creative? If we reverted to Polányi's above assertion, the short answer would be a sound "no", because, as the renowned philosopher of science, Karl Popper (1968: 8) put it:

"[T]here is no such thing as a logical method of having ideas, or a logical reconstruction of this process. My view may be expressed by saying that every discovery contains «an irrational element», or «a creative intuition», in Bergson's sense."

In other words, we know that intuitive insights (Dörfler and Ackermann, 2012; Dörfler and Eden, 2019) play a significant role in human creativity, they appear to be a necessary ingredient, and they belong in the realm of tacit knowledge, therefore AI Creativity, in a human mode, is impossible. However, it is worth considering whether there can be AI Creativity in a way that is different from how humans do it. In order to explore this further, it is useful to reconsider the AI track record so far and how these relate to the definition of creativity.

There are many claims about how AI will create at the finest level of human creative performance, such as writing a Shakespeare-level prose as suggested by Minsky (Amabile, 2019), and according to some this has already happened. One of the earliest acclaimed creative achievements of AI is the Logic Theorist (LT) coming up with a proof for one of the theorems in the Principia Mathematica that is according to Alfred North Whitehead "more elegant" than the one he and Bertrand Russell provided. This was definitely something new and useful—the two criteria of creativity. However, if we use the original definition of creativity by Teresa Amabile, as a novel and useful idea, it has a hidden third requirement: it also has to be an idea. While the details of how the LT did this requires some technical knowledge, it is easy to see that the process is transparent and fully explicit—contrary to how we see the human creative process. Can it help if we ask an appropriate group of judges to evaluate whether an AI outcome is creative and to which extent? The inadequacy of the Turing test suggests that this is not the case. To elaborate this, let us look at the two great game achievements, namely Deep Blue defeating Kasparov and AlphaGo defeating Lee Sedol.

In both cases there was a master-stroke, that shocked the human players and was highly praised by the chess and Go experts respectively. In the case of Deep Blue, a programmer later on said that there was a glitch in the system, caused by a bug that was subsequently fixed, which did not allow Deep Blue to choose one of the evaluated steps, so it went ahead with a random step instead. As in the Chinese Room argument, it was Kasparov who put the sense into this step. AlphaGo had a move against Lee Sedol that corresponds to all the rules but was never made by a human Go master. The reason is that Go has an enormous number of possibilities (and therefore it is more complicated, although less complex than chess), and the tradition evolved toward playing line 3 or 4 in particular situations and nobody ever played line 5. However, as AlphaGo, during its "training period", played some 300 billion games (which would be many grandmaster lifetimes) against itself, it built a database of moves, and the surprising move had a higher probability for a win in that particular situation. A first look at these stories suggests that there was no creativity, in the human sense, demonstrated by AI in either case. However, if that was all we could learn from this case, it would not be worth going into such detail—there is much more.

If we relax the definition of creativity to include "ideas, problem solutions, or other outputs" (Amabile, 2019: 3), the two moves, as well as the above mentioned mathematical proof provided by LT, could qualify. I would be still hesitant to consider these achievements creative, as it is fairly visible how they were achieved, and looking up maximum probability from a big table intuitively does not appeal as creative. If we think about this, the move by AlphaGo was new to the human Go masters, but it was not new for AlphaGo—it must have made it many times, if it had high probability for a win. Was it a new move when AlphaGo made it the first time? It probably was, but randomness seems to have more to do with this than creativity.

Nevertheless, these examples do give us an important glimpse into how AI can play immensely useful role in human creativity. AI is really good at quickly analyzing large amounts of data, identifying patterns in vast sets of facts, things that require precision.

That is why Thomas Davenport (2018: 44) says that AI is “analytics on steroids”. Humans are not very good at these, and even if we managed to do it, it would take far too long. What AI is not so good at, is judging which pattern is, or may potentially be, significant in the situation at hand – but human experts excel at this. For example, if an oncologist and a chemist are working with some chemicals trying to achieve an effective cancer treatment, AI may produce an incredible number of combinations of chemicals at hand, but it cannot judge which resulting compounds may be of interest, beyond meeting predefined specifications. However, the oncologist and the chemist may figure out, looking at some of the characteristics of the new compounds produced by AI, whether there are some new (unexpected) combinations which may be useful for curing cancer. Furthermore, human experts may also notice that some of the resulting compounds may be useful for treating kidney stones, for instance. The reason that AI could not pick up on these is that the solution is in a different realm than the original problem. The knowledge of the two doctors was necessary for figuring out the significance of the new pattern uncovered by AI. Similarly, designers in fashion, furniture, automotive and other industries use AI today for coming up with potential new models. While AI can deliver new models (by rearranging existing patterns), it is the designer who chooses which one is aesthetically appealing. Therefore AI can provide pre-processing in the sense of identifying and organizing patterns, and so can add immense value to the human creative process.

There is an additional perhaps less trivial value that AI can add. High-level human creativity is closely associated with domain (discipline or problem area) expertise. Such high level of expertise takes time to develop. And, like all the Go grandmasters in the world, experts often lock themselves up “inside the box”, imposing unnecessary but conventional limitations. In fact, the triumph of AlphaGo revitalized the world of Go: human Go grandmasters are reporting new moves, new strategies, increased openness, and going beyond the approaches of the traditional schools. Consequently, although it may sound initially surprising, AI can help us think “outside the box” in the best sense of the term.

Concluding Remarks

In the prologue of his book called *The Emperor’s New Mind* (paraphrasing Hans Christian Andersen), Roger Penrose (1989) introduces a mythical supercomputer Ultronic, which was set up in the Grand Auditorium, and the citizens were invited to ask any question. As the computer knew everything, it should be able to answer any question. People felt “bashful, afraid to seem stupid”, intimidated by such a super-smart entity, so nobody dared to ask any question ... until the thirteen year old Adam dared... The story is concluded in the Epilogue of the book, Adam asked the super-smart computer what did it “... FEEL LIKE”, to which Ultronic responded that it didn’t see what and couldn’t even understand what Adam was getting at and then everyone was laughing. The supercomputer with 1017 logical units, which was supposedly making it more intelligent than the combined intelligence of the whole country, could not handle such a tough question.

In this chapter, I have provided a personal view of AI in the context of creativity. I have tried to paint a rich picture of AI, not aiming at comprehensiveness or immaculate precision of the details, but rather at intuitive understanding of the essence. However, I also tried to be faithful to what can be known about AI, bringing it closer to the reader. Herbert Simon (1995: 508) said that it was time to stop philosophizing and to focus on empirical (and particularly experimental) testing. While I agree with Simon about the value of empirical work, I think that philosophizing about AI was never as timely as it is now, in order to delineate beliefs from facts and to demystify what AI can actually do. Unless we do this, AI is in the danger of becoming a brilliant solution in search of an appropriate problem (as Theodore Roszak said about computers in general), rather than a brilliant solution to a range of problems in a variety of areas, including creativity.

'Arts bias' refers to the tendency to think of creativity in terms of aesthetic forms such as painting, music, poetry and theater. While art-centric views were dominant up until the early 20th century, understandings of creativity have since expanded to include activities as diverse as home crafts, warfare, manufacturing, management, advertising and technology, among many others. Current debates over arts bias are symptomatic of the ambiguities surrounding evolving definitions of creativity. Significantly, many of the newer 'arts' of creativity differ from conventional understandings of aesthetic creation in a key way: they bring to modern definitions of creativity (see "originality and effectiveness" in [Runco and Jaeger, 2012](#), p. 92) a distinctly utilitarian aspect. Technology, especially data-driven, information storing and social connection systems, have emerged as the defining example of 21st-century creativity.

Art is frequently perceived as inherently lacking in usefulness. In a discussion of the "outstanding permanence of art", Hannah Arendt noted that the proper intercourse with a work is not "using" it. As art is "removed from the wants and exigencies of daily life", she argued that the intense worldliness and consistency of art serve as a lasting symbol of the stability of human artifice; as something "immortal achieved by human hands" (p. 167–168).

Notions of immortality and permanence are closely tied up with longheld ideals that artists possess special, imaginative powers, such as the divine inspiration afforded to poets as described by Plato, for example. These conceptions of elite skill (typified by classical, Romantic and early 20th-century artists such as Mozart, Samuel Taylor Coleridge and Picasso), are precisely the kind of ideas which some current researchers view as "damaging", "incorrect", "flawed", potentially 'harmful', ([Patston et al., 2018](#), p. 367) and 'dangerous' ([Cropley, 2014](#), p. 368). In their view, bias toward artistic disciplines risks obstructing more diverse and productive understandings of creativity. This is especially so given that "the global economy is shifting to a new paradigm", and the world of work now requires students to prepare for having many careers and developing high levels of creative intelligence to avoid losing work to automation ([Patston et al.'s p. 367](#)).

Yet as authors such as Oli Mould assert, in 21st-century media and government discourses there has been a strong focus on, indeed, a bias toward, forms of creativity that drive neoliberal capitalism, such as technology, design, advertising and finance ([2018](#)). The 2015 United Nations Creative Economy Report for example showed that already in 2012 new media and design made up 69% of all recorded creative output globally, while the performing arts made up only 1% (p. 2). Mould argues that conceptions of 'the creative industries', 'the creative class' and 'creative cities' (coined by Richard Florida and adopted by OECD governments since the turn of the century) have helped to shape neoliberal policy and discourse.

The tension between acts of creation which are useful and acts which only illuminate something about the human condition (especially experience and emotion) is the central issue which will be explored in this entry. It will be argued that non-human, machine-led creativity in art-making and other domains also raises questions about bias. Computational artmaking challenges long-held presumptions that creativity is anchored in, and must emerge from, human feeling and being in the world.

The New Frontier: Machine-Led Creativity and Art

Although computational creativity is not naturally associated with the ideas, perceptions and feelings of traditional art ([Jones, 2018](#)), engineers have for some time been working on replicating artistic forms. Their attempts to control and catalog the ways art is produced and consumed perhaps even suggest an implicit and ongoing bias toward art. Such pursuits also invite reflection about why artworks are valuable in the first place, and what – beyond economic gain – is really driving the desire to apply new tools, such as algorithms, to artmaking.

In 2009 Pablo Gervás documented how programmers were focused on mastering a wide range of cognitive abilities to achieve the "complex intellectual product" of storytelling. The skills that interested artificial intelligence workers included: the perception of space and time, the invention of multi-dimensional characters, and the successful design of make-believe worlds within which intricate plots could play out ([Gervás, 2009](#), p. 50–51).

Since machines have begun to try to 'manufacture' artistic creativity, data has become increasingly central to storytelling production. However, Sebastian Wernicke has proposed that human insights and instincts are still far from obsolete ([2016](#)). He compared

Netflix's globally successful *House of Cards* (created by playwright Beau Willimon) and Amazon's *Alpha House*, which also depicted US politics but relied more exclusively on data about television consumption to make its artistic decisions. Wernicke showed that the gut instinct to go with a concept which had sprung from Willimon's human imagination illustrated something about the current limits of machines to originate and conceive of stories worth telling.

Wernicke's conclusions mirrored Tricia Wang's research on "the human insights missing from big data" (2017). Wang also stressed the importance of 'intuition' in developing and marketing new technology products, as well as the significant difference between a machine's capacity for reflecting complex patterns of what already exists, versus a human's ability to conceptualize new trends based on lived experience and consciousness.

Data and machines have also been used to produce fine art. The French group Obvious have been using what they call "a different type of paintbrush" to produce 'Rembrandts' from the datafication of hundreds of existing originals (Cabrera, 2018). In London an exhibition called *Chance and Control: Art in the Age of Computers* (2018) showed the now extensive evolution of art-making with machines dating back to the 1950s.¹ According to computer arts author Catherine Mason the collection showed how "working with code does give the capability to produce random events; pseudo-random number generators can be introduced into the program to produce unexpected elements within a planned structure" (2018).

Proponents of computer art face the criticism that such work is only a "poor pastiche" of what is innately human (Jones, 2018). As Gervás noted, the unique qualities of what constitutes artistic creativity go beyond the new, the beautiful, the interesting and the pleasurable – they reflect and appeal to an essential human quality: "A sunset may generate a totally new combination of colors, possibly unexpected, but it would not be considered creative." (2009, p. 49)

Creativity and Neoliberalism

As noted earlier, Mould's work raises the possibility that there is a neoliberal bias in current meanings of creativity. Alongside Stefan Kratke (2010) and Thomas Osborne (2003, see further reading), Mould has posited that the rhetoric of neoliberal creativity overshadows more diverse thinking about political agency, social infrastructure and value, and disguises the way capitalism absorbs all competing ideas into the neoliberal frame. Mould uses the example of a Pepsi advertisement featuring Kendall Jenner, which appropriated protest movements such as Black Lives Matter into a celebrity-driven corporate selling strategy.

The dominance of neoliberal ideas in creativity can also be seen in *Forbes* magazine's 2018 article discussing the "innovation capital" of the world's most creative and genius leaders, including Jeff Bezos of Amazon, Mark Zuckerberg of Facebook and Tim Cook of Apple (Allen, 2018). Each of these business executives has influenced the world by providing consumers with extraordinarily novel and useful products or services that make use of complex amalgams of data and algorithm permutations. Their innovations enable creative people and new forms of creativity (such as photography using iPhones), but while they excel in driving economic activity, negative impacts such as the diminution of privacy and teenagers' exposure to peer pressure and bullying (Child Law Practice, 2013) have been felt.

Tomas Chamorro-Premuzic has suggested that internet-centred economics and digital modes of human interaction have facilitated "a glut of unoriginal and trivial content", augmented people's self-perceived creativity and even 'killed' creativity (2015). Chamorro-Premuzic traces this to the use of emojis and other "pre-determined functions to express our views – liking, sharing, and, in some cases, disliking" which promote laziness and more consumption-based behavior. Thus, while technology has helped to democratize modes of communication and knowledge acquisition between classes, it has also created a society which is "horizontal, frictionless, decentered, heterogeneous and (as) networked as possible" for optimal consumption (Mould, 2018). The implication in these views is that technological creativity has begun to work in ways that restrict, control and dumb down human behavior, with too much data now sitting in the hands of technology leaders.

Dark Creativity and the Ethics of Artistic Creativity

One issue that sits at the center of art bias is creativity's tenuous relationship with 'the ethical'. Ideals of beauty, truth and edification in art prescribe a basically moral character to creativity, even though artistic work has also made significant contributions to destructive political and social systems. From sculpture to mosaic to metal-work to painting to theater, many works have aestheticized the lives of elite rulers and their military conquests (think of the Column of Trajan in Rome, 113 C.E. or the pyramids of Egypt) and underrepresented stories about people from lower-socio economic strata. Fairytales, a very different type of cultural production, have also widely propagated ideals of patriarchal domination and material wealth (O'Neill, 2018). A more extreme example of art's ability to cause harm is Leni Riefenstahl's celebrated film *Triumph of the Will* (1935) which glamorized the power of the Nazis in 1930s Germany. More recently, narrative and cinematic imagery in advertising have been crucial to the 'nudging' of human behavior toward certain patterns of consumption (Yeung, 2016, pp. 119–127).

As Arthur Cropley notes, referring specifically to the cases of Hitler and Stalin, it is still hard to value the 'novel effectiveness' of dark acts such as war and terrorism (McLaren, 1993) in the same terms granted to artists (2011, p. 141). Associations of creativity

¹The Victoria and Albert Museum's first computer art exhibition was titled *Cybernetic Serendipity*.

with art as a moral act endure, and many of the works which have survived throughout history (such as Greek plays and poems) show art to be capable of raising continually pertinent moral questions. Many theatrical works - both modern and ancient - provide a common space in which truths are contested and in which criticism is freely expressed. Modern fields such as arts psychotherapy have furthermore helped to heal, engage, motivate and fulfill vulnerable or outcast members of the community such as prisoners, abuse victims and refugees (Wadeson, 2010; see further reading). Research on children's education has shown that art facilitates many capacities required for learning such as "problem solving skills, creative thinking skills, evaluation skills, adaptation, assimilation, and association skills which are vital in a child's ability to apply the information that is taught in the classroom." Researchers emphasise that the positive emotional experience of creating and sharing art is critical for understanding others' emotions and communicating." (Scott, Boggan and Harper, 2011, p. 87).

While much of the art market is still operated by an exclusive intellectual class who trade works as luxury commodities (the global art bazaar rose to \$63.7 billion in 2017 from \$56.9 billion in 2016) other sectors of the traditional arts are falling from visibility. In 2017 more galleries closed than opened according to the Art Basel Report (Freeman, 2018; UBS [3AD]). Funding for the performing arts remains in steady decline in countries such as the US, the UK and Australia (Brisbane, 2015; Evans, 1999; National Endowment for the Arts, 2009) and experts note that arts organizations more broadly are struggling to perform like businesses to cope with the demands of neoliberalism.

Conclusion: Thinking About Art in an Expanded Field of Creativity Research

The diversification of creativity research since the 1950s arguably has introduced exciting and more democratic possibilities for thinking about novelty, innovation and human potential. James S. Fishkin's 'deliberative polling' for example has allowed citizens to engage more meaningfully on local and national issues (2017). Similarly, the introduction of microfinance for women in Bangladesh has fostered new and progressive social possibilities (Murshin and Murshid, 2018). Social media platforms have been at the vanguard of movements in societies previously trapped under limited political conditions. These and other examples demonstrate that it would indeed be significantly limiting in the present era, to think of creativity as only artistic.

Perplexingly, as creativity becomes more diverse and inclusive, 'levels' of creativity are declining according to research using Torrance tests. "Creative thinking is declining over time among Americans of all ages ... The decline begins in young children, which is especially concerning as it stunts abilities which are supposed to mature over a lifetime" (Kim, 2011, p. 293). Mueller et al.'s study on the workplace revealed an unexpected rejection of creativity, as some corporations appear to want more creativity but hold implicit biases against ideas which challenge more practical or unoriginal options (2012, p. 17). These results no doubt intersect with a range of social factors, but perhaps also point to the inherent and ongoing ambiguity surrounding the identification of creative potential.

The issue of arts bias is indicative of the present era. Difficulty lies in working out how to reconcile instinctive ethical and elite characterizations (grounded in art) with more utilitarian and productive, modern or destructive forms of creativity. The technology that drives neoliberal capitalism, and that tries to replicate the imaginative qualities of art, fits more closely with modern definitions - but some of it threatens to restrict and diminish future human creativity. Technology tends to reflect the wants and exigencies of a given era (Arendt, 1969, p. 167), whereas some art has sustained a permanence in human culture. For all its 'inutility' art often actively seeks to encourage the continual asking of ethical questions, and reminds us to second-guess new paradigms and systems of value.

Introduction

A recent innovation in education, often called the STEAM movement, is predicated on the proposition that adding Arts to Science, Technology, Engineering, Mathematics and Medicine will improve STEMM learning and make future scientist and engineers more creative (NAS Report). The assumption behind the STEAM movement is that artists are more creative than scientists and therefore have something to teach STEMM professionals about how to be creative. Oddly, the equation is rarely considered in its commutative formulation, in which science and technology might be harnessed to stimulate artistic creativity. Historically, the science-to-art transfer is probably the more common direction in which interactions have occurred. This essay examines what characteristics arts and sciences share; what characteristics they do not; and why these things matter for understanding creativity in both sets of disciplines as well as for the hybrid practice of “art-science”.

Two Cultures?

There is little doubt that many artists have been scientists and many scientists, artists. One need only think of the archetypal Renaissance men, Leonardo da Vinci and Andreas Vesalius; the astronomer-composer William Herschel and Nicholas-Jacque Conté (the artist who invented of conte crayons as well as dozens of chemical and mechanical methods) and mathematician, philosopher, theologian, humanitarian Maria Gaetana Agnesi during the 18th century; Alexander Borodin, the composer and chemist and, biologist-artist-anthropologist Ernst Haeckel during the nineteenth; or mathematician-engineer-architect-composer Iannis Xenakis, MIT artist-mathematician Erik Demaine, and physicist-dancer-scifi-novelist-entrepreneur Catherine Asaro in the twentieth. Yet there have been persistent arguments for decades about whether such polymathic individuals were actually *combining* arts with sciences or simply practicing each separately. Perhaps geniuses are simply good at many things so that their multiple talents tell us nothing about whether the disciplines they practice have any cogent or coherent links (see POLYMATHS, this volume). For arts and sciences to meld into something that can be identified as an art/science hybrid, integration must be demonstrable.

Some eminent scholars have averred that the arts and sciences are so different as make such hybridization or synergy impossible. C. P. Snow, himself a very successful novelist, politician and physicist, famously characterized the arts-sciences divide in his 1959 Rede Lecture, *The Two Cultures*: “Literary intellectuals at one pole—at the other scientists, and as the most representative, the physical scientists. Between the two a gulf of mutual incomprehension—sometimes (particularly among the young) hostility and dislike, but most of all lack of understanding Two groups—comparable in intelligence, identical in race, not grossly different in social origin, earning about the same incomes, who had almost ceased to communicate at all ...” (Snow, 1959, 1–2).

The historian and philosopher of science Thomas Kuhn widened the divide a decade later by arguing that arts and sciences fundamentally differ in terms of their accumulation of knowledge. Whereas the sciences accumulate positive knowledge upon which each subsequent advance is made, and whereas the sciences have clearly stated paradigms defining legitimate problems, the appropriate techniques for investigating them and objective means of evaluating possible solutions, Kuhn argued that the arts use subjective forms of inspiration and evaluation that do not accumulate a growing body of knowledge or develop paradigmatic practices. While Kuhn further characterized revolutions in science as drivers of progress toward increasing understanding of nature, he characterized them in art as mere rejections of everything that had preceded (Kuhn, 1977).

Most recently, the embryologist and philosopher Lewis Wolpert has argued that no matter what superficial similarities may seem to link the arts and sciences, a closer look inevitably reveals that in terms of methods, results and utility, arts and sciences share nothing of substance (Wolpert, 2005). “Art has contributed zero to science, historically,” says Wolpert (Lythgoe, 2007). The participants of the 1980 Nobel Conference on *The Aesthetic Dimension of Science* (1982) had reached the same conclusion.

One difficulty that is often raised is that the products of arts and sciences are supposedly incommensurable. Arts are often characterized as being intuitive, subjective, sensual and unique; sciences as logical, objective, intellectual and universal. Consequently, some scholars have argued that if you give ten scientists the same problem, they will, if they succeed, produce identical results but if you give ten artists the same scene to paint and they will produce ten different pictures. Another supposed difference concerns the inevitability of scientific discovery and the uniqueness of the artistic vision. Nobel prizewinning physicist Werner Heisenberg reportedly said that had he not lived, someone else would have invented his indeterminacy theory but if Beethoven hadn't lived, we would never have the *Opus 111*.

If these positions were correct, then integrating arts and sciences is doomed to failure and there should exist no viable examples of hybrid art-sciences practices.

Domain Specificity Versus a Universal Creative Process

Various generalizations can be made about those who perceive the Two Cultures to be an accurate description of the relationship between arts and sciences and those who do not. To begin with, many of those who perceive an unbridgeable division work (or worked) in only one of these domains and have (or had) little or no training in the other. Notably, those who work (or have worked) in both domains almost universally describe them as being very similar. Ignorance, then, is a major barrier to communication across the Two Cultures, a point Snow himself made in his original essay on the topic.

A second division arises between those who focus on disciplinary products versus those who focus on creative process (Root-Bernstein, 1984a). Physicist Freeman Dyson has argued that, "The analogies between science and art are very good as long as you are talking about the creation and the performance. The creation is certainly very analogous." (Curtin, 1962, p. 139) Musician and composer Gunther Schuller, who was present for Dyson's remarks, responded, "Absolute similarities, just absolutely no difference," (Curtin, 1962, p. 142) Nobel prize-winning physicist Murray Gell-Mann (Physics, 1969) similarly asserted that, "Artists experience the same creative processes as scientists." (Weisburd, 1987, 299) He elaborated: "Everyone agrees on [where ideas come from]. We had a seminar here [at the Aspen Physics Center] ... including several painters, a poet, a couple of writers, and the physicists. Everybody agrees on how it works. All of these people, whether they're doing artistic work or scientific work, are trying to solve a problem." (Judson, 1980, 21) Only when the analytical focus is on the *products* of the arts and sciences do people generally assert that arts and sciences domains are irreconcilable; paintings or compositions are not only expressed in different symbol systems, media and materials than are scientific experiments or mathematical theorems but have different purposes.

A similar basis exists for the split among cognitive scientists between those who assert that creativity is domain-specific and those who believe that it is domain-general. Howard Gardner is an example of an investigator who has argued that people in different creative "domains" think differently and, more importantly, think in ways that mirror the types of things they produce. Gardner has defined about nine distinct types of intelligence according to whether each exists in isolated brain regions; is essential to mental function; is susceptible to specialized symbolic encoding or expression; can be developed in highly purified forms in prodigies, savants or other exceptional people; and is susceptible to psychometric or experimental identification (Gardner, 1983, 9). In his book, *Frames of Mind: The Theory of Multiple Intelligences* (1983), he initially identified seven such "intelligences" and identified each with a range of related professions: linguistic (e.g., poets and novelists); musical (musicians and composers); logico-mathematical (scientists and mathematicians); visuo-spatial (artists); bodily-kinesthetic (dancers); inter-personal (politicians, social workers); and intra-personal (psychologists). Subsequently, to account for biologists and farmers, Gardner tentatively suggested a "naturalist" intelligence; and for religious and philosophical thinkers an "existential" intelligence (Wikipedia, Theory of Multiple Intelligences). While admitting that eminent individuals may develop polymathic abilities in more than one intelligence [Gardner, 1983, pp. 7–10], Gardner's typology fundamentally draws absolute distinctions between how people in different disciplines such as the arts (visuo-spatial), dance (bodily-kinesthetic), creative writing (linguistic) and sciences (logico-mathematical and naturalistic) *think*. If such distinctions are as fundamental as Gardner originally drew them, then it is difficult, if not impossible, to imagine how arts (broadly conceived to include music, dance, creative writing, and visual and plastic arts) could inform the sciences, mathematics or technology, or vice-versa. Indeed, from Gardner's perspective, it would be a mistake to lump all the "arts" together in a single cognitive category, or to lump the various sciences such as biology and mathematics.

The Root-Bernsteins (1999) in their book *Sparks of Genius: The Thirteen Thinking Tools of the World's Most Creative People*, have responded to Gardner with the argument that, at a cognitive level, all creative people think similarly regardless of the discipline in which they perform their creative work. However, creative people choose to translate their insights into different forms and formalisms depending on the audiences with whom they are trying to communicate. Products of creative thinking are often generated by "intelligences" and using symbol systems and brain functions that are completely different than the ones used for their expression. Einstein, whose professional work was all expressed in words and equations, said, "No scientist thinks in equations." (Infeld, 1941, 312) "No really productive man works in such a paper fashion ... These thoughts did not come in any verbal formulation I very rarely think in words at all." Thoughts came, he elaborated, in visual and kinesthetic forms that he saw as reproducible dynamic images and muscular feelings: "A thought comes, and I may try to express it in words *afterwards*." (Wertheimer, 1959, 184)

Similarly, Martha Graham, one of Gardner's examples of a "bodily-kinesthetic" thinker, did not devise her dances through body thinking, but from reading, viewing paintings and listening to music: "I would put a typewriter on a little table on my bed, bolster myself with pillows, and write all night ... I get the ideas going. Then I write down, I copy out of any books that stimulate me at the

time many quotations and I keep it. And I put down the source." "I steal from the best where it happens to be – Plato, Picasso, Bertram Ross. I am a thief." Like Einstein, she then continued, "First there is the concept. Then there is the dramatization of that concept which makes it apparent to others." (Root-Bernstein and Root-Bernstein, 2003). One of Gardner's archetypal "linguistic" thinkers, T. S. Eliot, similarly wrote that his ideas did not originate in words, but in images and feelings and even music: "With a poem you can say, 'I got my feelings into words for myself. I now have the *equivalent* in words for that much of what I have felt.'" (Eliot, 1963, p. 104) Most creative people explicitly draw this distinction between modes of creative thinking and the need for a translation process that produces an equivalent of their insight in some defined medium (Root-Bernstein and Root-Bernstein, 2004). The creative product need not, then, reflect the creative process.

In contrast to Gardner, the Root-Bernsteins (1999) claim that all creative people rely on a common mental "toolkit" consisting of observing, imaging, abstracting, pattern recognition, pattern forming, analogizing, dimensional thinking, empathizing, body thinking, modeling, playing, transforming, and synthesizing. What differentiates disciplines is not different forms of thinking or different cognitive abilities, but rather differences in the constraints imposed on the products an individual creates by the tools, symbol systems, evaluation procedures, training and social norms that surround their production and dissemination. They reinterpret Gardner's findings concerning domain thinking as choices involving communication and dissemination of ideas and agree that most creative people master only a limited range of these, often only one. Thus, while the creative process and its cognitive bases may be common to people in all disciplines, the disciplinary knowledge required to *express* a creative insight is usually domain specific.

Moreover, neurological studies demonstrate that brain functions such as language, visuo-spatial ability, musical processing, and mathematical ability are often co-localized, undercutting another of the key discriminators that Gardner originally used to distinguish between "intelligences". Cognitive skills, perversely, appear to be both localized *and* distributed within the brain. Indeed, the study of synaesthesia suggests that every sensory and symbolic system is capable of both voluntary and involuntary mixing in every possible permutation (Cytowic, 1993). People can feel tastes, hear visual images, see and taste sound, perceive black-and-white symbols of any kind (words, math, music) in color, and so forth. From a neurological perspective, such synaesthetic combinations make possible any imaginable combination of arts, sciences, and technologies.

The fact is that many people who work across domains report that their thinking processes are similar or identical in all. Consider Georges Urbain, a synthetic chemist, the discoverer of the element lutetium, and a professional sculptor and composer. Urbain pointed out that chemists are as creative as composers and in the same way. All music is made up of a handful of notes combined in an almost infinite variety of combinations just as all of the physical world is made up of a handful of elements that make up every compound and mineral. Chemists and composers both explore the possible combinations in an attempt to discover novel and useful effects. Thus, "The musician combines sounds in the same way the chemist combines substances ... musician and chemist reason in their respective fields in the same way, despite the profound difference of the materials they use" (Urbain, 1924).

Similarly, MIT metallurgist Cyril Stanley Smith wrote that he often used what might be called "artistic" methods in his thinking and research because they complemented the usual "scientific" ones: "I have slowly come to realize that the analytic, quantitative approach I had been taught to regard as the only respectable one for a scientist is insufficient ... the richest aspects of any large and complicated system arise from factors that cannot be measured easily if at all. For these, the artist's approach, uncertain thought it inevitably is, seems to find and convey more meaning" (Smith, 1981, p. 9).

The physicist and sculptor Robert R. Wilson provides yet another example. He not only invented and designed the high-energy particle accelerators for FermiLab in Batavia, Illinois, but also the building in which it was housed, most of the sculptures that decorated its grounds and hallways, and even the utility poles providing the facility with its electrical power, commenting that: "In designing an accelerator, I proceed very much as I do in making a sculpture. I felt that just as a theory is beautiful, so, too, is a scientific instrument—or that it should be. The lines should be graceful, the volumes balanced. I hoped that the chain of accelerators, the experiments, too, and the utilities would all be strongly but simply expressed as objects of intrinsic beauty" (Wilson, 1992; np). Elsewhere, he elaborated: "If one thing is clear it is that there is much in common between what the creative artist does and what the scientist does" (Wilson, 1978; np).

Can Artists Make Scientific Discoveries or Invent New Technologies?

So, if the thought and creative processes of scientific discovery are very similar or identical to those of artistic creativity (broadly conceived as including creative writers, dancers, composers, musicians, and other performers), why do artists not make scientific discoveries and technological inventions? (see DISCOVERY, this volume; see POLYMATHY, this volume). Contrary to the opinions of Wolpert and the 1980 Nobel Conference cited above to the effect that artists have never contributed anything of substance to the sciences, these contributions are astonishingly numerous and important (Root-Bernstein, 2000).

Artists have discovered or invented perspective (the process of mapping a three-dimensional image onto a two-dimensional surface) and anamorphosis (the process of mapping any shape or image onto any other), which both have broad applications to mapping objects in cartography and in cinematography and, more surprisingly, to the biology of growth and form: D'Arcy Thompson employed anamorphosis to explain evolutionary relationships in his classic book, *On Growth and of Relative Growth Form* (1917) while Julian Huxley used it to explain fetal-to-adult developmental patterns in *Problems of Growth* (1932). Similarly, architect Buckminster Fuller's invention of geodesic domes had a direct influence on the discoveries of spherical virus structures and ultrastable spherical carbon compounds generically called "buckyballs", while sculptor Kenneth Snelson's invention of

tensegrity resulted in the innovations in the understanding of cellular architecture by Harvard's Don Ingber as well as a slew of engineering innovations such as the Kurilpa Bridge in Australia.

Artists are also responsible for inventing many optical puzzles and illusions such as Archimboldo's "faces" made out of bowls of fruit or stacks of books, "impossible figures" such as Escher's endless staircases, or Marcel Duchamp's "rotoreliefs", some of which appear to rotate in opposite directions simultaneously. These optical puzzles and illusions are often employed by modern experimental psychologists for investigating neurological and cognitive functions. Artists also invented diverse techniques for displaying motion ranging from zoetropes and kinetographs to motion pictures. Camouflage, both as a biological concept involving selection of organisms to mimic their environments, and as a technology for hiding soldiers and their equipment during war, was the brainchild of the painter Abbott Thayer. Another artist, Jonathan Kingdon, whose only degree is a Masters of Fine Arts, has revolutionized the study of evolutionary theory by producing hugely synthetic works integrating animal coloration, communication, and behavior with biogeography and paleontology – not incidentally, earning him a position as a Senior Research Associate in the Department of Zoology of Oxford University although his only degree is a Masters of Fine Arts. Yet another artist, Wallace Walker invented an entirely new realm of geometry called "kaleidocycles" as a design student at the Cranbrook Academy of Art, which he then collaborated with mathematician Doris Schattschneider to develop (Hagan, 1991).

Artists and musicians have also produced many inventions that we take for granted. Robert Fulton, who invented the steamboat, and Samuel Morse, the inventor of the telegraph, were two of the most widely acclaimed American painters before they turned to inventing. Their artistic methods are clearly evident in their invention processes as Brook Hindle has made clear in his book *Emulation and Invention* (1981). The first viable color photographic process, Kodachrome, was invented by a pair of professional musicians, Leopold Mannes and Leopold Godowsky. The wildly successful inventor James Dyson has only one advanced degree and that is a Master of Fine Arts. Actress Hedy Lamarr and composer-musician Georges Antheil invented frequency hopping, which is the basis for one of the most widely-used encryption algorithms for electronic communications currently in use by both commercial and military institutions. The invention of pointillist techniques by neo-Impressionist painters was the direct inspiration for the development of pixelization in electronic media. Programming was invented by weavers who invented punched cards to create tapestry designs on automated looms. In fact, modern electronic chips are made by means of three artistic techniques that long pre-date the electronic age: silk screen printing, etching, and photolithography. So common are such fundamental discoveries and inventions that the MIT-trained engineer-artist-musician Robert Mueller has written in his book, *The Science of Art* (1967), that, "Art may be a necessary condition for constructing the new consciousness from which future science gets its structural realities to match nature, in which case it is more important than we generally admit."

Paradigm Shifts and Multiple, Simultaneous Discovery in the Arts

The fact that artists can and do make scientific and technological contributions, often by using artistic and design methods, suggests that Kuhn and Heisenberg were incorrect to maintain that the arts produce unrepeatable variations without accumulating positive knowledge. Recall that one their basic arguments is that had Beethoven not written Opus 111, no one else would have; every artistic production is unique so that ten painters will produce ten different paintings, even when painting the same scene. The arts do not have the equivalent of paradigms and therefore do not progress.

The bases of Kuhn's and Heisenberg's reasoning can, however, be challenged. Is the Opus 111 more unique than Heisenberg's first paper stating the indeterminacy principle? Consider an example in which it is known that had not one scientist discovered a principle, someone else would have. Kuhn himself has pointed out in an essay in *The Essential Tension* (1977) that as many as fourteen different scientists had claims to have "discovered" the first law of thermodynamics. However, each scientist based that claim on a different set of observations and expressed the principle in a different formulation using unique data in an idiosyncratically written publication that, aside from a statement of conservation of energy, had little similarity to any of the others. So, when Heisenberg said that if he had not discovered the principle of indeterminacy, someone else would have, he was certainly not saying that someone else would have written *exactly the same paper* in exactly the same words. The fact that every painting or composition is unique is not something that differentiates arts from sciences: every scientific paper – and every mathematical proof – is also unique and exemplifies the particular style(s) of its author(s). Compare Charles Darwin's first essay on evolution by natural selection with that, published simultaneously and in the same journal, by Alfred Russell Wallace for a good illustration.

The differences between arts and sciences also disappear when comparisons are made not between individual works, but between *conceptual inventions* such as the first law of thermodynamics, the principle of indeterminacy, or the invention of the calculus and the invention of *movements* such as Impressionism, cubism, kinetic sculpture, polyphony or twelve-tone composition. Just as the sciences are characterized by simultaneous or multiple discoveries of the same principles and phenomena, so are the arts. Beethoven was not the only composer writing in his style, so if Beethoven hadn't lived, then we would recognize one of his contemporaries as the outstanding representative of "his" style. If not Mozart, then Salieri. Igor Stravinsky and Arnold Schoenberg spent most of the first half of the 20th century squabbling over which of them had invented twelve-tone musical composition and even recognized that its invention was inevitable: "Schönberg once told [Rosalyn Tureck] that if he had not developed 12-tone music, someone else would have, and that his work was a natural and historical extension of Mahler's" (Weisburd, 1987). Georges Braque and Pablo Picasso never agreed on which of them invented cubist painting. Kinetic sculptures were invented almost simultaneously in Italy by Giacomo Balla and Fortunato Depero, in Russia by Naum Gabo around 1915, and mobile sculptures simultaneously by Alexander Calder and George Rickey in the US, and Jean Tinguely in France, during the 1940s. Buckminster Fuller and

Kenneth Snelson never agreed on which one invented the sculptural principle of tensegrity. Claimants to the invention of electronic music include Lejaren Hiller, Jr., J. R. Pierce, Claude Shannon, and Max Matthews, Raymond Scott, Iannis Xenakis, and many other scientists and engineers who had musical training and access to the first computers during the 1950s. So, contrary to Kuhn and Heisenberg, there is just as much a logic of development from one artistic movement to another as there is a logic of development from one scientific innovation to the next. Artists of all types do build on the innovations of their predecessors just as scientists stand on the shoulders of their mentors (Root-Bernstein, 1984b).

Notably, the fact of simultaneous discoveries in both sciences and arts also addresses Kuhn's argument that arts do not have paradigms based on accumulated sets of problems and their corresponding methods, techniques and approaches to solutions. In fact, every new movement in the arts builds, as Schoenberg said, on previous methods and poses new problems that have not yet been addressed. Thus, the history of the arts is one of an ever-expanding set of tools for addressing ever-broader ranges of human experience and emotion (Root-Bernstein, 1984b).

Art/Sciences Intersections

Thus far I have mainly examined how the arts have influenced the sciences and technology, but it is equally the case that the sciences and technology have influenced the progress of the arts. So much has been written about the geometrical bases of perspective drawing and the scientific bases of color theory in the arts that some of these influences may seem obvious from a modern sensibility. However, many connections are less well-known, though equally pervasive and influential. For example, Louis XIV and his minister Colbert formally placed scientists into creative industries such as the Sevres china and Gobelins tapestry factories, helping to make France the world leader in the production of these products. One consequence of this strategy was that during the 19th century, the chemist M. E. Chevreul was assigned to help the Gobelins factory improve the colored yarns used in weaving its tapestries and discovered the artistic principle of color complementarity widely adopted by 19th and 20th century artists and designers. Indeed, scientists such as the Nobel Prizewinning chemist Wilhelm Ostwald and the physicist Ogden Rood were major developers of the color theories used by modern artists.

At around the same time, a huge shift occurred in paint manufacture. Through the middle of the 19th century, most artists made their own pigments and paints by grinding various natural materials into fine powders emulsified in oils or water. The invention of the paint tube permitted mass manufacturing of paints by industrial chemical firms and, not incidentally, permitted painters for the first time to explore *plein air* painting. Equally revolutionary was the invention aniline dyes at the end of the 19th century that introduced the first of many classes of synthetic pigments, greatly broadening the range of colors accessible to artists. Further artistic innovations followed close on the heels of computer visualization tools as well. Nobel Prizewinning physiologist Roger Guillemin was possibly the first individual to use a computer to produce art, helping to initiate the computer-art movement.

Equally revolutionary changes accompanied scientific and technological progress. The invention of the first electronic musical instruments began during the late 19th century as musically-trained scientists such as Nobel laureate Walther Nernst began to apply electricity to understanding sound production. Concurrently, music benefited from the scientific study of the differences between natural harmonic ("just" or "Helmholtz") tuning versus tempered scales by biophysicist Hermann von Helmholtz and Nobel laureate Max Planck. The chemist Lejaren Hiller was the first person to program a computer to generate its own musical compositions, helping to kickstart the electronic music revolution during the 1960s. Biophysicist Gerald Oster discovered the principles controlling the production and perception of aural binaural beats, which has since become a regular feature of electronic music compositions.

Less well-documented, but equally pervasive, has been the use of scientific and technological ways of thinking by artists. A few random examples: Some of Shakespeare's most memorable lines, such as "nothing will come of nothing," turn out to have been inspired by the recently invented zero (Tammiet, 2014, pp. 55–62). Emil Zola transformed the structure of the modern novel by attempting to recreate it in the form of the physiologist Claude Bernard's philosophy of positive science. The French sculptor Auguste Rodin wrote that, "I have come to realize that geometry is at the bottom of sentiment or rather that each expression of sentiment is made by a movement governed by geometry. Geometry is everywhere present in nature ... The entire rhythm of the body is governed by law." (Petersen, 2001, p. 9) 20th century Futurist sculpture and the invention of kinetic sculpture are equally imbued with technology and its principles; Surrealist painting, with the fourth dimension on the one hand and biological forms on the other; Cubism with relativity theory.

These examples demonstrate that there is no fundamental difference between the creative thinking of the scientist, the artist, the composer, and the writer. Historian of technology Thomas Hughes has noted that, "the invention of machines, devices and processes by metaphorical thinking is similar to verbal creation, but the fascinating possibilities have not been much discussed, probably because persons interested in language are rarely interested in technology." Similarly, James McAllister and others find that the use of aesthetic criteria in the sciences, engineering, and the arts are virtually identical, and that the notion of beauty in science may be as essential as a motivation for discovery, and as a criterion for evaluating novel ideas, as it is in the arts (McAllister, 1996). "Artists and scientists alike need to employ both rational and intuitive approaches, adds [Nobel laureate Murray] Gell-Mann. 'Many problems transcend disciplines and demand a fusion of the two ways of perceiving.'" (Weisburd, 1987)

Burton and his colleagues, have formally studied transfer of skills and knowledge between arts and sciences and perhaps deserve the last word on the cognitive connections that link arts and sciences: "Arts learning, involving as it does the construction, interweaving, and interpretation of personal and socio-cultural meaning, calls upon a constellation of capacities and dispositions

that are layered and unified in the construction of paintings, drawings, poems, musical compositions, and dances. Many of these same competencies and dispositions are implicated in other subject domains where they coalesce in equally distinctive forms: mathematical, scientific, linguistic - in the organization of different kinds of meaning, insight, and understanding. What is critical is not that capacities and dispositions transfer, but that they are exercised broadly across different knowledge domains and that no subject has prior rights over any other subject. To diminish one is to diminish the possibility and promise of them all." (Burton et al., 2000, 255)

Formal Arts/Sciences Programs

For many of the reasons discussed above, formalized arts-sciences programs have evolved over the past couple of decades to take advantage of perceived benefits of the integrations of these sets of disciplines. The concept of STEAM, an integration of Arts into STEM education was mentioned in the introduction. Various people take credit for inventing the acronym including John Maeda, former President of the Rhode Island School of Design, which implemented a STEM-to STEAM program in 2008; Harvey White, co-founder of both Qualcomm Inc. and Leap Wireless International Inc., also laid claim to having invented the acronym about the same time; and Georgette Yakman, a graduate student at Virginia Polytechnic and State University used the acronym $ST\sum M$ in a paper that year. Such integration has found other labels as well. The U. S. National Science Foundation funds some programs in the STEAM area but was prohibited from adopting the STEAM acronym due to lobbying by agriculture professionals who wanted the A to stand for Agriculture, so NSF has allowed the acronym "SEAD" instead, which stands for Science Engineering Arts and Design (e.g., <https://sead.viz.tamu.edu>). The European Commission decided on STARTS, for Science, Technology and the ARTS, and offers prizes in collaboration with Ars Electronica in Linz, Austria (the premier arts-and-technology forum in the world), the BOZAR Center for Fine Arts in Brussels, Belgium and The Waag center for Technology and Society in Amsterdam, The Netherlands (<https://ec.europa.eu/digital-agenda/en/ict-art-starts-platform>; <https://www.starts.eu>; <https://ars.electronica.art>; <https://www.brusselsmuseums.be>; <https://waag.org/en/home>) Artist-inventor Todd Siler invented and trademarked the elided term "ArtScience" in 1994 (long before Harvard artist-biotechnologist David Edwards published a book of that title) building an educational program around it called "Think Like a Genius" (also trademarked). Various groups such as the SciArt Initiative in the US and the SciArt Organization in the UK have utilized some version of a sci-arts combination. Integrating arts, sciences and technologies has become a recognized movement among both practitioners and teachers of these disciplines.

One of the more pressing issues facing this movement is finding joint spaces in which to practice combined activities. Arts materials, facilities and lessons are generally easily accessible to anyone regardless of educational background, so that STEM professionals desiring to explore artistic methods and concepts generally have a low barrier to entry. Exceptions exist for technologically sophisticated arts such as glasswork, some types of ceramics, etc., but, in general, adding arts to STEM subjects and practices is less difficult than working in the opposite direction. Artists desiring to create art out of scientific materials (bioarts, chemarts, transmedia arts, electronic arts, etc.) often need access to a scientific laboratory, which is much more problematic at present and may present additional barriers such as technical and safety training, chemical-, tissue-, or animal-use approval, and so forth. Thus, at present, the number of stand-alone arts-sciences programs is very small with the most notable being Coalesce: Center for Biological Arts at the University of Buffalo (Paul Vanouse); SymbioticA, the Centre of Excellence in Biological Arts in the School of Anatomy and Human Biology at the University of Western Australia (Oron Catts); Open Labs at Science Gallery, Dublin, Ireland; MIT's Media Lab; The Laboratory at Harvard University and *La Laboratoire* in Paris (David Edwards); the ArtSci Lab at the University of Texas, Dallas (Roger Malina); and the Art and Science Laboratory in Sante Fe, New Mexico, (James Crutchfield). In Spain, the main driver of artscience integration is VIDA | Art and Artificial Life International Awards.

As with any inter- or trans-disciplinary undertaking, one of the challenges for people bridging arts and sciences is finding reputable places to publish novel findings. Specialized journals devoted to the intersections of arts and sciences have also evolved. The first and best-known is LEONARDO, the Journal of the International Society for Arts, Sciences and Technology, which was founded by kinetic artist and aeronautical engineer Frank Malina in Paris in 1968. More recent additions to the field include *SciArts Magazine*, *The Art and Science Journal*, *The STEAM Journal*, *The International Journal of Arts and Technology*, and *The Journal of the Society for Art and Science*. However, one of the major challenges that art-science integration faces is that the resulting products do not neatly fit existing means of display and dissemination so that novel hybrid platforms are being designed that exploit combinations of print, online access, holography, video and sound technologies in addition to integrated studio/laboratory and laboratory/gallery spaces.

The overarching purposes of art-science integration has been summarized by Robert Root-Bernstein, Adam Brown, Todd Siler and Kenneth Snelson in a LEONARDO editorial. Their main points are: "ArtScience involves understanding the human experience of nature through the synthesis of artistic and scientific modes of exploration and expression. ArtScience melds subjective, sensory, emotional, and personal understanding with objective, analytical, rational, public understanding. ArtScience embodies the convergence of artistic and scientific processes and skills, not from their products One who practices ArtScience is both an Artist and a Scientist simultaneously, and one who produces things that are both artistic and scientific simultaneously We must teach Art, Science, Technology, Engineering, and Mathematics as integrated disciplines, not separately The mission of ArtScience is the re-integration of all knowledge. The goal of ArtScience is to cultivate a New Renaissance." (Root-Bernstein et al., 2011)

Glossary

Associative Theory An explanation of creative thinking as the process by which disparate elements come together in new combinations for a useful purpose.

Convergent Thinking The process of bringing together information focused on solving a problem, especially problems that have a single correct solution.

Divergent Thinking The process of generating a variety of associations to a word or solutions to a problem.

Incidental Learning Unplanned or unintentional learning in which ideas or relationships, previously seeming to be irrelevant, are later associated.

Historical Foundations

Associative theory holds that creative ideas occur when disparate elements come together to form a new idea or solution to a problem. There is a general consensus in the field today that having a broad search process that enables a variety of associations to occur helps creativity. The importance of broad associations in the creative process has been a central component of many theories of creativity, including associative theory, which will be reviewed in this chapter.

The associative theory of creativity explores the ways in which ideas or solutions to a problem might be generated and how those ideas are linked together in the mind. Historically, philosophers, scientists, and psychologists have pondered the importance of associations in the creative process. Associationism was first a philosophical idea asserting that mental processes operated by the association of one state with its successor states. British associationists including John Locke and David Hume maintained that this principle applied to all mental processes. Ideas were said to be associated in the mind according to certain laws including contiguity and resemblance. Ideas could therefore lead to further ideas; this served as the understanding of mental functioning in general.

Alexander Bain wrote of the idea of incubation, when new combinations of elements can sprout from that which is already in an individual's mind. Imagine ideas in a person's mind, free-floating and continuously bumping into each other and combining. Sometimes, ideas will combine in ways that are not new, useful, or of any particular interest; however, other combinations may

be a unique or novel solution to a problem, and grab our attention, such that the idea becomes conscious and recognized as creative. Albert Einstein spoke of “psychical entities” which made up thoughts and how the combining of these entities was the “essential feature of productive thought.” Such perspectives on the importance of combining already existing elements in new ways can be viewed as the influential precursors to associative theory.

Mednick's Associative Theory

In 1962, Sarnoff Mednick published his associative theory of the creative process, stating that creative thinking was the process by which disparate elements come together in new combinations for a useful purpose. A creative solution to a problem comes about by bringing together multiple ideas which only when combined in a new way become useful as a viable solution. A combining of more remote elements is viewed as more creative than the combining of more similar items. For example, the Beijing National Stadium designed for the 2008 Summer Olympics, known colloquially as “the Bird’s Nest”, combined the traditional needs of a stadium with the model of a nest, thus bringing together two remote concepts into one creative product.

According to Mednick, a person can produce creative solutions through any of three processes: serendipity, similarity, or mediation. A creative solution stems from serendipity when associative elements are evoked by a person’s situation and are accidentally put together. Fortuitous discoveries, such as when US Navy engineer Richard T. James accidentally knocked a spring off his work table and invented the Slinky, are considered serendipitous. A creative solution might also be produced through similarity, such as when associative elements are evoked because of their similarity to another element, such as with words that rhyme. Lastly, creativity might arise from the process of mediation, in which associative elements are evoked through the mediation of a third common element. For example, a medical diagnosis might serve as the mediating link between multiple symptoms which might otherwise appear unrelated.

Components of Creative Associations

Mednick identified a variety of variables that could contribute to the likelihood of someone coming to a creative solution or making a novel association, with a strong focus on individual differences: (1) the need for associative elements, (2) an individual’s associative hierarchy, (3) the number of associations one makes, (4) the influence of cognitive and personality styles, and (5) the process of selecting a creative combination. Each is discussed below in more detail.

The Need for Associative Elements

To make novel associations between elements or ideas, one must have elements or ideas in mind with which to work. Simply put, one cannot put two things together if one does not have two things. As Mednick stated, “an architect who does not know of the existence of a new material can hardly be expected to use it creatively.” Moreover, the more associative elements to which one has access, the more permutations and combinations are possible. Thus, individual differences in experience, memory, knowledge, and verbal ability have the potential to affect one’s level of creativity depending on the task.

The Individual's Associative Hierarchy

The associative hierarchy depicts the ways in which different individuals will produce associations to a problem (see Fig. 1). For example, if asked, “how many ways can you think of to use a tire?”, most individuals begin by giving some common associations, such as: “put it on a car to drive” and “make a tire swing”. Those individuals with steep associative hierarchies then show a marked decline in their ability to keep thinking of ideas, while those with flatter hierarchies continue to produce ideas, some of which are more unlikely or uncommon, such as “use it as a snow tube for sledding” or “shred it as the footing for a playground”.

Figure 1 Possible associative hierarchies according to Mednick’s associative theory.

Mednick stated that the person with the flatter hierarchy can be said to be the more creative the individual, while the person with the steeper hierarchy is less creative. Not only does the person with the flat hierarchy produce more solutions in total, but also tends to produce more original solutions. This pattern of response generation for the more creative person, the person with the flatter hierarchy, is explained by postulating that in this creative person's mind, more ideas are connected, but the associations between the ideas are not as strong. This set up allows for a more interconnected mind, such that a given problem will lead to a wider range of solutions including those which are less common. In other words, word associations for the more creative individual will be less stereotyped. For example, a person with a steep hierarchy might respond to "table" with typical associations like "cloth" or "dinner", but then run out of associations, while a person with a flatter hierarchy might continue on to an answer such as "ping pong" or "water". For the creative individual, associations may be weaker but they are farther reaching.

The associative hierarchy leads to two important implications. First, a high concentration of associative strength in only a few responses can limit future creativity. For example, the greater the number of occasions on which a person has solved a problem using one particular solution, the less likely the individual will be to produce a creative solution in the future. Given the problem of a flat tire, and elements consisting of a spare tire and a wrench, who would generate possible solutions much beyond the tried and true response, "change the tire"? In other words, given the same problem, the same materials, and a solution that worked last time, one will have a steep associative hierarchy. This means that given the same problem and the same materials, an individual who is new to the scene or possesses less knowledge may be more likely to generate creative solutions than someone who has been presented with the same problem many times before.

Secondly, the hierarchy posits that most people, no matter the level of creativity, will begin by giving typical, unoriginal answers. Thus, it seems that novel associations are only produced after one has depleted their reservoir of more obvious ideas. This notion that the more creative ideas will come later in the associative process suggests that when an individual is faced with a problem, there is a benefit in taking enough time to get past the obvious solutions in order to reach those more remote connections.

The Number of Associations

The greater the number of associations an individual can produce for a given problem, the more likely their chances are of producing a creative solution. This notion is not completely separate from the associative hierarchy described previously. A person with a flat associative hierarchy is more likely to produce novel associations not only because of their weaker but broader associations in general, but also due to the sheer quantity of responses that they are more likely to generate. A possible explanation for this phenomenon, based on associative theory, is that the more associations that are made, the more likely it is that a link to a new associative element will be found, that will continue facilitating more associations. For example, a person naming animals may begin with unoriginal answers like "cat" and "dog", but once they think of "cow", they suddenly have a bridge to a host of other barnyard animals not yet listed.

The notion that it is usually only after the stereotyped responses have been depleted that more creative solutions are uncovered, is referred to as the serial-order effect - the tendency for the creative quality of ideas to increase over time. However, this is not always the case. [Beatty and Silvia \(2012\)](#) found that fluid intelligence moderated this effect, such that as fluid intelligence increased, the serial-order effect diminished, indicating that time was not necessary for more intelligent participants to produce creative ideas. The authors suggested that this effect could be explained by those participant's ability to inhibit salient but unoriginal ideas that typically come to mind at the beginning of the task.

Personality and Cognitive Styles

Given that a greater number of associative elements and number of associations produced are both likely to lead to more creative solutions, associative theory must also grapple with how an individual's previously learned methods for approaching a problem and their personality style in terms of persistence or motivation might influence their likelihood of producing creative solutions. Individuals who score higher on the personality trait of Openness to Experience, a dimension of the five-factor personality model referring to an individual's propensity to be open to new aesthetic, social, or intellectual encounters, are more creative. In a study of cryptic crosswords, [Friedlander and Fine \(2018\)](#) review how individual differences in openness to experience and sensitivity to external stimuli can impact the degree to which a person either inhibits or remains receptive to incidental information. Those who tend to pre-filter material they deem irrelevant may effectively reduce their likelihood of making lateral associations or accessing their associative networks.

Selecting a Creative Combination

What causes a person to pick one solution to a problem over another? Mednick's answer to this question reaches back to the definition of a creative product as something both novel and useful. The "usefulness" of a solution distinguishes a creative idea from a unique but random one. For example, when asked "How many ways can you use a tire?", it is implied in the question that solutions must include a tire and a way of using it. Therefore, answering "rubber" does not meet the "uses" requirements the way that "put it on a car to drive" does. However, using a tire on a car is far from a novel response. Conversely, while the answer "give it as an engagement ring" might be original (no other respondent provided this answer), it is not a realistic use for a tire, and therefore should not be considered as a truly creative solution.

Mednick asserted that the novel association or solution achieving the closest fit with the set of problem requirements is the solution which gets selected. For example, a diagnosis that is able to explain all of a patient's symptoms will be chosen over

a diagnosis that explains only half the patient's symptoms leaving the other half unexplained. The solution explaining all the patient's symptoms is the more useful. According to Mednick, the creativeness of a given solution can be seen as some function of the number of requirements that the product meets. A solution meeting all the requirements is more creative than a solution only meeting half.

Measures

The Remote Associates Test

An advantage of the clear predictions made by associative theory about individual differences and creative products is that they are testable. In 1967, Sarnoff Mednick and Martha Mednick operationalized associative theory's definition of creativity with the Remote Associates Test (RAT) (See [Remote Associates](#)). Since its inception, it has been used to test a variety of predictions about creative thinking and the problem-solving process.

The original RAT consisted of 30 items administered with a 40-min time limit. For each item the subject was presented with three words which seemed to be unrelated (playing, credit, report) and the subject was asked to produce a fourth word that would serve as the associative connection between the disparate words presented (card). The test items were intended to make the subject think creatively, by taking given associative elements and creating a novel combination by providing the mediating link. Mednick emphasized the importance that the links be strictly associative such that a subject must use creative thinking and not logic, concept-formation, or problem-solving to reach the same solution. A subject's score was calculated as simply the total number of correct answers out of 30.

Mednick reported the Remote Associates Test to have high reliability with samples of undergraduate males and females. Original validity studies found that high RAT scorers got good grades from teachers rated as flexible and low grades from teachers rated as dogmatic, and vice versa for those subjects with low RAT scores. Mednick also reported significant positive correlations between high creativity and social attitudes of liberalness. In follow-up papers, RAT scores were also found to correlate with the Creativity Rating Scale (CRS) on which professors were asked to rate the creativity of their graduate students. The RAT was not found to correlate with the Miller Analogy Test (MAT) nor with scores of GPA.

In addition to being a measure of individual ability, the RAT is a useful tool for studying the creative problem-solving process, particularly the concepts of insight, incubation effects, and fixedness on the wrong solution. Fixation on incorrect words can occur when an answer closely associated with one or two of the clues blocks access to more remotely associated words that are needed to reach the correct solution. Experiments by Nitin Gupta and colleagues showed that such fixation can be deliberately induced by priming subjects with commonplace associations that are unhelpful for reaching the solution. For example, for the RAT item Arm, Coal, Peach (answer: Pit), misleading associates such as arm-leg, coal-furnace, and peach-pear were presented as examples of potential associations, rendering the task more difficult. Consequently, test takers who can avoid a bias towards high-frequency potential answers and access more remote possibilities (i.e., those with what Mednick referred to as a flat associative hierarchy), will perform better on RAT puzzles.

However, critiques of the Remote Associates Test have also been prevalent. The test does not seem to take into account motivation or other intrinsic factors, including those which Mednick wrote about himself, such as past experience or the number of associative elements available which could also affect someone's apparent level of creativity. Later research found that an individual's ability to solve RAT items was significantly related to a variety of cognitive abilities, most notably verbal ability. [Daniel Fasko \(1999\)](#) has made similar arguments, citing research showing weaknesses in Mednick's original theory. For example, individual differences show that highly creative people tend to avoid repeating themselves more than less creative people. Fasko asserted that Mednick's associative theory may require some revisions to address the complexity of creativity.

Word Association

In a follow-up paper published in [1964](#), Mednick and colleagues continued to explore associative theory using a continual word association task. In this line of research, instead of looking at the associative hierarchy of an individual, the associative hierarchy of individual words were examined. The associative hierarchy of a word is defined by group word association norms. Thus, a word is said to have a steep associative hierarchy if it elicits only one dominant association and then many other associations all of low response strength. In contrast, a word is said to have a flat associative hierarchy if it does not elicit any single dominant response, but instead elicits many responses all of somewhat equal frequency. Studies of individual differences among words found that high frequency words elicited more responses than did low frequency words, and that nouns elicited more responses than did adjectives.

Research findings using both continual word association and the Remote Associates Test examining associative theory and the associative hierarchy notion has been mixed. Mednick's hypothesis was that highly creative individuals would respond relatively slowly but steadily, emitting many responses during continual word association. Instead, although the high RAT scorers did produce more responses, they also did so at a consistently more rapid pace than other groups and participant's level of creativity, as measured by the RAT, related directly to response frequency. Furthermore, when individual creativity was measured by divergent thinking and self-report, rather than by the RAT, associative hierarchies were not found to differ between the low- and high-creativity groups, but rather the high creativity people simply produced more answers and therefore more uncommon answers ([Benedek and Neubauer, 2013](#)). Results such as these suggest that the interpretation of creativity as merely associative behavior is too simple, suggesting the need for revisions to Mednick's original theory.

Other Measures

A wide variety of other association measures exist to further the understanding of associations in creativity. The Kent-Rosanoff Word Association test (KRWAT) is another word association measure. Participants respond to each stimulus word with the first word that comes to mind. The measure has shown significant correlations with other creativity ratings for engineering honor students and research scientists. This measure was the first to have objective scoring and norms presented in frequency tables; however, the test was criticized for not incorporating individual differences in responses due to factors such as socioeconomic status, age or education level.

Another related measure is [Gianotti et al. \(2001\)](#)'s word pair list, in which participants are shown a word pair that is either indirectly related (e.g. cat - cheese), or unrelated (e.g. corn - helmet). Participants are then asked to produce a third word that could serve as the connective link. In a modified administration of this task, participants were asked to judge the associative distance between the given words on a rating scale from 1 (strongly related) to 6 (without any relation), and complete several other creativity tasks. In support of Mednick's theory of individual differences in associative hierarchies, participants with higher creativity scores estimated the distance between the unrelated word pairs to be smaller than less creative people ([Rossmann and Fink, 2010](#)).

Semantic distance between responses can also be assessed using latent semantic analysis (LSA) in which software is used to determine the probability of a given word occurring in a specific context and assigning a coefficient of semantic similarity. This process can be used to measure individual differences in associative abilities by calculating semantic distance of responses generated during verbal fluency tasks, such as listing synonyms for the word *hot*. Those individuals with larger semantic distance scores would be considered individuals flatter associative hierarchies. Studies using LSA found support for the effects of associative abilities on the creative quality of divergent thinking responses.

One important development is that tasks such as the Remote Associates Test are now seen as involving some divergent thinking while individuals scan for broad associations, but are largely focused on convergent thinking, where information is brought together to form a single, correct solution. Insight tasks would also fit this category of convergent thinking. In contrast, creativity and creative potential are increasingly measured using divergent thinking tests in which subjects are asked to generate as many responses as they can think of. Divergent thinking tests are therefore more open-ended than the RAT, but serve as another way to explore individuals ideational patterns. Aside from the sheer number of ideas presented by a person (fluency), the individual answers might also be scored in terms of their flexibility, originality, or elaboration. Current measures used in this area include J.P. Guilford's Alternate Uses Task, Michael Wallach and Nathan Kogan's adaptation of the Alternate Uses Test for children, and the Torrance Tests of Creative Thinking (TTCT). How well a person performs on divergent thinking tasks was related to their self-reported creative achievement and expert ratings of creative performance, as well as predicting creative accomplishments.

Recent research found that associative abilities (i.e., high dissociation and associative combination ability) predicted half the variance in divergent thinking performance; such findings support the notion that in addition to being able to access remote associations, one must be able to combine them in adequate ways ([Benedek et al., 2012](#)).

Incidental Learning

In his 1967 paper on incidental learning, Patrick Laughlin suggested that the process of forming, retaining, and using remote associations is essential in both creativity and incidental learning. Laughlin defined incidental learning as a situation in which apparently irrelevant ideas or relationships are later be associated with each other. Based on associative theory, it is therefore predicted that a more creative individual will display better incidental learning.

Two possible factors are hypothesized to explain the connection between creativity and incidental learning. First, Laughlin suggested that a highly creative person might have greater perceptual sensitivity to the seemingly irrelevant stimulation presented in an incidental learning scenario. Secondly, it is also possible that the highly creative person is better able to retain the stimuli from the scenario in a more accessible form in order to use the information later for solving the incidental learning task. This notion seems closely linked to Mednick's ideas about the availability of information previously stored. In line with associative theory, Laughlin's incidental learning study results were interpreted as "reflecting wider deployment of attention and less screening out of irrelevant past experiences by high creatives during problem solving."

Neuroscience Approaches

Recent findings from neuroimaging research (fMRI) have identified the default mode network (DMN) as the brain system involved in spontaneous, self-generated thought. [Beaty et al., \(2016\)](#) concluded that this is the neurological network involved in mind wandering and letting one's thoughts roam. It is involved in the incubation stage of creativity where remote associations can occur.

Beaty and colleagues also identified a different network, the executive control network, that is involved in the evaluative, editing stage of creative tasks. The executive control network brings cognitive control and critical thinking to creative tasks. The RAT has a large component of evaluative thinking in reaching the correct word. Divergent thinking tasks involve both types of networks: an open-ended phase of idea generation and an evaluation phase that identifies solutions. Recent fMRI studies have found

a dynamic coupling between the DMN and executive control network when people engage in creative activities. Creative people can go back and forth between these two networks more easily than less creative individuals. Interestingly, these recent findings are consistent with early psychoanalytic theories based upon observation of creative individuals.

Psychodynamic Perspectives on Associative Theory

Classic psychoanalytic theory adds another perspective to understanding associations and creativity. In essence, individual differences in comfort with primary process ideation accounts for the number and originality of associations. Primary process thinking is, according to Robert Holt, drive-laden oral, aggressive, and libidinal content and illogical thinking related to that content. It is a developmentally early, primitive system of thought, heavily affect-laden, and not subject to logic. Sigmund Freud thought that if individuals repressed “dangerous” thoughts and wishes, then there would be a general intellectual restriction. In a primary process mode of thinking, ideas are easily interchangeable and attention is widely and flexibly distributed. Therefore, there should be a broader search for associations for individuals comfortable with primary process ideation. There is strong empirical support for this hypothesis on various divergent thinking and association tasks, especially with male participants.

The psychodynamic perspective is consistent with Mednick’s associative theory. It provides one explanation for why some individuals have such a steep associative hierarchy while others have flat hierarchies: there is a looser connection among ideas for individuals who have easier access to primary process thinking. There is not such a strong bond among ideas and images so that more flexibility-of-thought and associations can occur.

For true creative production to occur, individuals must go back and forth between primary process thinking and more logical thinking (secondary process thinking). This ability to access primary process in a controlled fashion is Ernst Kris’s concept of “regression in the service of the ego”. Because production of a novel and useful product requires original associations and evaluation, both broad associations and critical thinking are necessary. The RAT actually measures both of these processes. As previously mentioned, the RAT is not a pure association task. It has been categorized as closer to an insight task because it requires broad associations but then has one correct answer that must be selected. In psychodynamic terms, one must access primary process thinking and then use critical evaluation to select the right response. Creative production is, at least, a two stage process.

In an attempt to test this assumption, [James Murray and Sandra Russ \(1981\)](#) used the RAT with college students, along with the Rorschach, scored using Holt’s well-validated primary process measure. The Adaptive Regression score on the Rorschach reflects both primary process content and the control of that content. This score significantly related to the RAT for the total sample and more strongly in the male participants ($r = 0.42$), independent on SAT scores. In addition, Adaptive Regression related to the RAT more strongly than to measures of divergent thinking. Murray and Russ concluded from this study that a two-stage process accounted for the cognitive operations underlying adaptive regression and the Remote Associates Test. The first stage was a generative stage while the second stage was an evaluative stage. These findings are consistent with the neuroimaging studies described above.

Mood and Associations

Affect and mood are important variables in influencing the range of associations a person makes. Dimensions of affect account for individual differences in range of associations but also can increase the frequency and originality of associations when manipulated. Much of the research in this area has used a mood induction paradigm. For example, a specific mood is induced by having individuals watch a movie, receive a gift, or think of a memory. In a series of well-designed studies, Alice Isen and her colleagues found that positive affect induction resulted in increased creativity when compared with control groups. She concluded that the positive affect cues positive memories and a large amount of related cognitive and affective content. This process results in defocused attention and a more complex cognitive context, which, in turn, leads to a greater range of associations and interpretations. In another study, Isen found that positive affect improved performance on the RAT, while results for negative emotions were mixed. Interestingly, in one study, she found that induced positive affect resulted in a broader range of first associations to neutral words. They were more unusual and diverse than for individuals in control groups. This is different from what one would predict from Mednick’s theory that common associations would occur first for everyone.

A few studies suggest that mild forms of negative affect could facilitate some kinds of problem solving tasks. In a recent meta-analysis of 25 years of mood and creativity research, Matthijs Bass and colleagues concluded that positive moods do produce more creativity than neutral moods if the positive moods are activating (happiness) and associated with approach motivation. It should be noted that for the majority of studies, the connection with positive mood is for divergent thinking. In contrast, there is some evidence that positive mood may actually lower convergent thinking. Negative emotional states that might inhibit creativity on divergent thinking tasks may enhance performance on insight tasks for which there is a single, correct solution.

There are other current theories about why the involvement of affect broadens associations. Gordon Bower’s associative network theory conceptualizes emotion as a memory unit. The activation of the memory unit aids in retrieval of events associated with it and primes emotional themes for use in free association. In a model by Issac Getz and Todd Lubart, the emotional resonance model, endocepts that represent emotion are attached to concepts or images in memory. These emotional memories are partially interconnected and can activate one another.

Research has also begun to explore whether the perceived pleasantness of the task itself plays a role. Zenasni and Lubart (2011), found that the number of ideas generated on a divergent thinking tasks was significantly related to the perceived pleasantness of the task. Such research suggests that the impact of emotions in creative performance may not hold a single answer, but rather depend on many factors including the nature of the creative task itself. One important implication of the research on mood and creativity is that breadth of associations can be altered by the involvement of emotion. The steepness of an individual's associative hierarchy is likely influenced by affect.

Conclusion

One test of a theory is the impact that it has had on a field. Using that criterion, Mednick's associative theory and the psychodynamic theory of association has been useful. Through theory and research, these conceptualizations focused the field of creativity on the importance of associations in creative thinking. It is now generally accepted that creative production is partially dependent upon having a broad search process and novel associations. The RAT has proven to be a valid measure of a specific type of creative thinking and has been used in many studies of creativity in adults. Mednick, especially, provided an important foundation, in both his theory and his test, for other research programs and theories to develop. Although criticized as being simplistic in its view of the creative process, it made a major contribution to the field. Current research and theories continue to focus on the important process of association in generating creative ideas. Neuroimaging studies in particular may help identify the specific role of associations in different types of creativity tasks.

Glossary

Asynchronicity An appropriate level of discrepancy that may stimulate creative thinking.

Cognitive dissonance Inconsistent cognitions that do not fit together and which motivate creative thinking.

Janusian Thinking Cognition that uses two or more contradictory ideas simultaneously.

Person-environment fit Joint influences of individual and setting with similarity between the two is expected to nurture creativity.

Tension Inner conflicts experienced as a result of interpersonal or intrapersonal mismatches.

Introduction

A considerable amount of knowledge accumulated in the literature on creativity comes from studies of eminent people whose lives and achievements are taken as a proof of their creativity. Historiometric studies and research on socially recognized creativity have provided useful information that help understand the dynamics of creative achievement. Asynchronicity emerged from this line of investigation and is apparent in some eminently creative individuals. It helps to distinguish creativity from expertise, giftedness, genius, or prodigiousness. It is also critical for understanding the personal, environmental, and domain-related foundations of creativity.

The concept of asynchrony was first discussed in detail by Howard Gardner and Constance Wolf (1988), who made a case based on their analysis of Pablo Picasso and Sigmund Freud. Later, Howard Gardner extended his analyses to others such as Stravinsky, Eliot, Graham and Gandhi in his book *Creating Minds*. However, the effects of asynchronicity had also been noted by other researchers who used synonyms such as tension, conflict, disequilibrium, or dissonance. This chapter attempts to show how the construct of asynchronicity has been interpreted in the field and how it relates to those other processes and to creativity.

Asynchrony refers to an appropriate level of disharmony or discrepancy that helps to stimulate creative thinking. Gardner and Wolf described how “strategic mismatches or asynchronies” may underlie creativity. They disagreed with the proposition that creativity is the “wake of the numerous interacting factors” and rather, contended that “creative efforts are more likely to arise when there is a certain tension or asynchrony among principal factors that underlie human behavior. It is this tension that gives rise to creative works” (p. 101). Asynchronicity or tension is not simply a situation that exists in creative people’s upbringing. In fact, creative individuals often seek it, whereas others tend to do the same for synchrony. Novelties, creations, and new perspectives may be possible for people with unusual or uneven profiles who can think outside the box and see the world in alternative ways.

Three Levels of Asynchronicity

There are different kinds of asynchronicity including but not limited to conflicts with family members, homosexuality, early difficulties in school, irregularities in cognitive development, sickness and loneliness in childhood. Gardner classified potential sources of conflicts in three levels: personal, impersonal, and multipersonal.

Personal Level

Asynchrony on the personal level can operate in several ways. The first is actually a sub-personal aspect, which is about genetic, neurological, and brain-related differences residing in creative minds. Attempts to explain such differences such as analysis of Einstein's brain after his death did not yield conclusive results or were abandoned later, as with the argument connecting creativity strongly with right brain function. Contemporary research underlines the importance of a whole-brain approach such as cooperation of default and executive functions. Research on people with brain injury and the case of autistic savants who can spontaneously find prime numbers in spite of being unable to perform basic multiplication or reading shows that neurological and neuroscientific research promises an explanation of unusual minds. One commonly emphasized unusual characteristic related to brain function is the dominant hemisphere which, for the most part, refers to the left hemisphere taking over sequential, analytic and verbal process whereas nondominant hemisphere processes are attributed to right-brain action involving simultaneous, visuospatial or synthetic processes. This design is subject to change, even reversal, when the person is left-handed. The fact that most people are right-handed, and creative artists prefer using their left hand (Preti and Vellante, 2007) can be explained by this unusual hemispheric asymmetry.

Another aspect of asynchrony at the personal level involves cognitive capacities and structures of creative people. As Gardner discussed in detail, creative people may either have unsurpassed levels of particular intelligences, as was the case with Picasso, who had very high spatial and bodily-kinesthetic intelligence with exiguous scholastic intelligence, or may possess an unusual blend of intelligences like Freud, who apparently had superior logical, intrapersonal and linguistic-verbal intelligence. However, asynchrony sometimes also comes from thinking processes. Some research relating creativity to *primary process thinking*, which enables free association and thinking with metaphors and symbols, rather than *secondary process thinking*, which is logical and goal oriented, is critical to understanding the moment of inspiration and the concept of incubation. Here, asynchrony involves the function of primary process thinking, which is regarded as an indication of regression serving the ego, while secondary process thinking would represent synchrony among a set of logical thoughts and assumptions. Creative people may differ in that they utilize and balance their primary and secondary thinking processes whereas most people suppress their primary processes and overemphasize the secondary process with aging.

The role of unusual cognitive patterns in creativity can be extended in different ways. Albert Rothenberg asserted that the creative thinking process involves *Janusian thinking*, which was defined as "the capacity to conceive and utilize two or more opposite or contradictory ideas, concepts, or images simultaneously" (p. 11). He argued that Janusian thinking is basically secondary process thinking that modifies primary process thinking by providing its "seeming ubiquity" and allowing "primary-process-like material to appear in consciousness". He interviewed Nobel laureates from several fields and concluded that the Janusian process plays a significant role in scientific creativity. He identified four levels of process: 1) motivation to create; 2) deviation or separation; 3) simultaneous opposition or antithesis; 4) construction of the theory, discovery, or experiment. Opposing ideas that emerge at the second and third level are often resolved and disappear at the fourth stage. The transition from the third to the fourth stage includes a state of asynchronicity or tension: "Strong motivation provides the drive to consider and conceive the inconceivable; emotional involvement, especially if it involves meaningful conflict, jibes with the cognitive tendency to focus on opposites and antitheses and bring these together simultaneously. The simultaneous opposition and antithesis, with the conceptual conflict retained among composing elements, seems to be isomorphic with emotional conflicts and other psychological processes" (p. 221).

Another critical quality of many creative individuals is their preoccupation with diverse modes of thought simultaneously. Acar and Runco (2015) reviewed these and others who agreed with this perspective and applied it to scoring of divergent thinking tasks. Divergent thinking accompanied by evaluative thinking or imaginative cognition paired with realistic cognition would mostly result in creativity, although they may not achieve that independently (Basadur, 1995). Arthur Cropley (1996) argued that creativity is the consequence of the joint influence of divergent and convergent thinking, which are seen as opposing thinking modes. He supported this hypothesis with the case of Vincent van Gogh, whose artworks became well-known after he learned basic techniques of painting. His artistic potential, represented by divergent thinking, would not have been fruitful had he acquired convergent skills. Mark A. Runco (1994, 1999) added that even incompatibility between such diverse modes of thought might be useful when tension is triggered.

Some empirical studies can also be approached as documenting asynchronicity emerging at the cognitive level. Roni Reiter-Palmon et al. (1997) examined the influence of cue consistency on problem construction. They found that the quality and originality of the solutions were higher in the presence of inconsistent cues. Likewise, Ella Miron-Spektor and her colleagues (2011) found that people were more creative when they were exposed to contradictions. It is reasonable to argue that tension springing from inconsistent cues or contradictions might elicit creativity. According to Keith James et al. (1992), tension frequently functions as a signal that indicates a need to fix, modify or resolve on the perceiver's part.

The third aspect of asynchrony on the personal level is non-cognitive, which is more about personality and emotions. The creativity literature lists numerous personality characteristics of creative individuals that can be related to marginality such as childlike nature, daydreaming, playfulness, contrarianism and nonconformity. Each of those characteristics can be seen as sources of

asynchronicity. Einstein is a remarkable case for the role of personality in creativity. Gardner argued that Einstein preserved his childlike nature and naïvety even as an adult, and this enabled him to approach problems in a different manner from others. In this way, he was able to ask the critical questions the answers to which he could find later. For example, the question “Why is the sky blue?” would be a childhood curiosity for many who later quit thinking of this question without searching for any answers. What makes Einstein and few others different is their unending interest in such basic yet significant questions that would lead to many scientific elaborations.

W. Ed McMullan (1976) argued that many creative people have “paradoxical personages” by which he referred to the coexistence of eight polarities in their personalities. First, most creative people tend to delay closure and are open to new ideas while at the same time they feel a strong urge to achieve closure and eventually form a gestalt. Second, they are inclined to swing between the modes of lateral thinking and logical thinking. Third, they can also merge the unconscious into consciousness which allows them to keep up “mindless perception”. Fourth, creative people are often fault finders and destructives, but they also reconstruct and make new syntheses. Fifth, they mostly have passion, but they also need to stay calm and reasonable. Sixth, they are both ego-centered and empathetic since they desire success, power, fame, and honor, yet are also altruistic, concerned about others and their well-being. Seventh, they are usually confident about their abilities and proud of their successes while they are humble and aware of their weakness and ignorance for the most part. Last, their insight emerges when they are in a state of relaxed attention, which is the moment of shift between work and relaxation. Likewise, Mihalyi Csikszentmihalyi (1996) discussed the complex personality of creative people as an integration of contradictory extremes. He argued that creative people are usually both energetic and quiet, smart and naïve, disciplined and playful, imaginative and realistic, extroverted and introverted, humble and proud, masculine and feminine, rebellious and traditional, passionate and objective, and suffering and joyful.

As for emotions, relationships with the opposite sex are mostly exploitive and temporary. In such cases, broken relationships were sometimes followed by suicides. As Arnold Ludwig (1995) showed in his search for the “Price of Greatness”, higher rates of suicide among members of the sample with exceptional creative achievement was one of the costs that some of them encountered. Also, several studies including meta-analyses (Baas et al., 2008; Davis, 2009) indicating a relationship between mood disorders and creativity can be looked at within the realm of personal non-cognitive asynchronicity. The frequent association of creativity with mental illnesses, specifically mood disorders, should be recalled here. Nancy Andreasen found that 80% of creative writers experienced a mood disorder like depression, mania or hypomania at least once in their lives.

Impersonal Level

The second level of asynchrony involves the domain of knowledge, the impersonal level, where creative individuals need to interact. Knowing about the domain is a necessity for contributing to or challenging it. Robert J. Sternberg views creativity as a process of “defying the crowd” where the creator resist against the pressure for compliance and conformity. There was no cubism, psychoanalysis or physics of special relativity before Picasso, Freud and Einstein learned about, influenced, mastered and evolved the domains, and eventually created their own domains. If they had been in complete agreement with their domains, they would not have revolutionized those domains. Therefore, discontent or dissatisfaction with the domain is oftentimes fruitful and can initiate epistemological changes in that field. A good example of this is Freud, who began with philosophy and switched to scientific medicine. Going through neurology, neuroanatomy and psychiatry, he came up with a new domain, psychoanalysis, which influenced many other domains from visual arts to political science.

Knowing a domain is a crucial aspect of creativity because learning process brings recognition of the gaps and inconsistencies regarding the content. Scientific creativity has a lot to do with the domain. In the sciences, many contributions arise from those gaps and inconsistencies in the domain. In physics, for example, Newton’s physics represented the core of the domain for a long time, and Einstein acknowledged that “The whole development of our ideas concerning natural phenomena [...] may be conceived as an organic development of Newton’s thought” in the article in which he discussed the limitations and weaknesses of Newtonian physics. However, creativity more than simply an outcome of extensive knowledge acquisition in a particular field. It is an important, but not sufficient condition. It takes one who mastered a field to challenge the knowledge base and redefine the domain (Kaufman and Kaufman, 2007).

Multipersonal Level

The third level of asynchronicity is the perspective of the field, which is the multipersonal level. Creativity does not come out of a vacuum. There may have been many creative ideas that remained unrecognized because the people who evaluated the work did not find them impressive and valuable. Such lack of fit between the creative person and the field might result in a fruitful asynchrony in cases which the creative people could resist the forces of the field and launched their own influence in spite of the price such as being alone like Freud. Mihalyi Csikszentmihalyi mentioned E. O. Wilson and presented his works as an example of attempts to construct a new domain called Sociobiology, connecting social sciences with evolutionary biology. Just like the examples above, he had severe disagreements with people within field. Another example of asynchrony at the multipersonal level is Hilde Domin, who is a famous poet and writer. She had to wait for six years to publish her poems because of the politics of the field. Her naïvety and lack of knowledge about a “literary mafia” helped her to sustain and have an independent literary career. This is why some people’s creativity is only recognized posthumously (Ludwig, 1995).

Dichotomous Classification

The asynchronicities exemplified above are simply based on Csikszentmihalyi's systems approach involving the interactive or dialectical relationship of the three elements: person, domain and field. Mark A. Runco preferred *tension* to represent the construct, and classified asynchronicities in two groups: intrapersonal and interpersonal. With this categorization, Runco related the personal level to intrapersonal tension that implies a misfit between the situation and its perception by the individual, or to inconsistent thoughts that associate the field and domain with interpersonal tension.

Intrapersonal tensions are crucial for creativity. Csikszentmihalyi used the term *cathartic originality* to describe the underlying processes of artworks. He argued that the discomforts that are rooted in repressed tensions of childhood may stimulate creative works after the individual becomes mature and better able to handle them. Unsurprisingly, psychoanalytic views on creativity have supported this argument. William G. Neiderland reported that psychoanalysts encounter common factors such as tragic early childhood experiences, traumatization and conflicts, loneliness, loss, and discontent with body image among creative people in their clinical experiences. Many creative people's response to such unfortunate experiences is a heightened emotional reactivity that evokes their awareness of already existing oversensitivity to internal and external stimuli. The feelings of being incomplete, ugly and deficient among creatively active individuals are often replaced by sensations of completeness, adequacy and strength through artworks. Martin S. Lindauer explained the stylistic changes of artists in the same way. Personal conflicts like physical or emotional handicaps are sometimes compensated for through artworks. The presence of grief, ordeal, pain and irregularities in biographies of some creative people confirm this notion.

In the intrapersonal case, further elaborations can be made. For instance, Leon Festinger called tension arising from two or more inconsistent cognitions *cognitive dissonance*. According to him, it is human nature to sustain an internal consistency among opinions and attitudes. This consistency is a state of consonance and equilibrium in which individuals are free of tension. With the emergence of new situations or the acquisition of new knowledge, existing cognitions are challenged, and individuals are motivated to reduce the dissonance and achieve consonance again. Therefore, the presence of dissonance functions as an antecedent condition that stimulates human cognition to a new synthesis. This is how cognitive dissonance may result in creative thinking. Colin Martindale hypothesized that creativity is related to resistance to cognitive dissonance in the sense that creative people, unlike most others, may not be motivated to achieve consonance. The more people tolerate novelty and deal well with incongruity and respond to it in a flexible way, the more they experience dissonance, taking advantage of it, and eventually, the more creative they become.

Is this the case in real life? Edward Boring, who wrote "Cognitive Dissonance: Its Use in Science", argued that "Any reader of Kepler's biography will wonder how the three great planetary laws could have emerged from so in consonant a mind, in which mysticism was mixed up with a passion for accurate observation, which perceived as one of its great intellectual achievements the spacing of the six planets in the solar system as related to the shape of the five regular geometrical solids, a mind which took astrology seriously, and which experienced ecstasy over both its true and false successes" (p. 683).

Cognitive dissonance theory makes it possible for creativity researchers to see the link between intrinsic motivation and creativity, given that Festinger regarded cognitive dissonance theory as fundamentally motivational. Since dissonance is discomforting, so it oftentimes functions as a source of arousal. The dissonance provides most people with a directional goal in terms of which they can either search for memories to support the desired conclusions or search out new knowledge to create a new explanation. The latter is actually how cognitive dissonance leads to the motivated reasoning resulting in creativity.

According to Jean Piaget, intrinsic motivation is preceded by certain cognitive operations. This occurs when individuals encounter new knowledge that they cannot understand. In this case, new ideas are not compatible with current conceptions, and disequilibrium emerges and continues until the individual assimilates or accommodates to reach equilibrium again. At that point, it is critical to point out that creativity is achieved as long as individuals can adapt to new information and expose themselves to perennial conflicts, even as they grow older. Morris I. Stein also acknowledged the role of disequilibrium claiming that it takes place at the beginning of the creative process.

Another kind of asynchrony is related to cortical arousal. Colin Martindale argued that the arousal system of creative people is unusual. He observed that their arousal level does not linearly increase with the arousal potential of the stimuli. At some point, there is a "dip" in their arousal, which seems to correspond to the moment of inspiration, unlike uncreative people, whose cortical arousal increases with the arousal potential of the stimulus. He showed that the EEG activity of creative people was lower during the inspiration phase than uncreative people whereas there was not any difference in the elaboration phase. He linked lower level of arousal with the unfocused attention that enables elaboration of several mental elements simultaneously.

Asynchronicities at the interpersonal level may occur in the family environment, too. Robert S. Albert and Mark A. Runco argued that incongruent parent-child relations can create tension, which enables the child to develop autonomy. Richard Koestner and his colleagues (1999) found that parental conflicts in the form of disagreements, rather than warm and liberal parenting, predicted adult creativity. From a factual standpoint, loose relationships of eminent physical and biological scientists with their parents as well as findings regarding the high rates of parental loss in the exceptionally gifted population seem to support this hypothesis. Sibling rivalry, family size, birth order and parental expectations are important factors to be considered as potential sources of asynchronicity at the interpersonal level.

Cultural marginality could also be mentioned under the umbrella of the interpersonal level. According to Thorstein Veblen, the intellectual success of the Jews in Europe is related to their cultural marginality. In Freud's case, he had to leave Austria because of

Nazi oppression. Before his life in France, Picasso lived in Spain and kept his ties with his native country. According to Csikszentmihalyi, a distinguishing feature of the centers of creativity throughout history was that they were at the crossroads of cultures and cosmopolitan life in those cities where diversity of thought and lifestyle is the rule rather than exception.

Asynchronicity Versus Person-Environment Fit

A frequently mentioned factor involved in creativity is the rule of “being in the right time and right place,” which refers to a good match of the person with familial, social, economical, political, or cultural surroundings. According to this view, the concurrent presence of these advantages paves the way for creativity. Creativity is defined as the outcome of the individual’s behavior in a context. Therefore, the joint contribution of person and environment should be taken into consideration. To exemplify this, a non-conformist individual within an environment that encourages or tolerates non-conformity would be a good match for creativity. However, the asynchronicity approach seems to disagree with the idea of person-environment fit.

According to asynchronicity, the coming together of several positive factors or coincidences may explain the emergence of prodigiousness or eminence, but not creativity. For this reason, the rule of “being in the right time and right place” works in the opposite manner for creative people: for creativity to emerge at least to some degree, the right time and place implies a context that brings somewhat lack of fit or disharmony. According to [Runco and Gaynor \(1993\)](#), the matching should be optimized so that an appropriate level of discrepancy for creativity is maintained. For this reason, Simonton described the best mentors as those who fall between the “too similar” and “too dissimilar” ends. Daniel Rubenson and Runco also argued that an optimal mix of individuals is necessary for creative productivity. This also means that too much as well as too little asynchronicity is mostly unproductive.

Unproductive Asynchronicity

In their discussion of the concept of asynchronicity, Gardner and Wolf asked the following question: “When does asynchronicity become counterproductive?” This question was legitimate, given research findings associating creativity with madness. Recent meta-analytic investigations by [Selcuk Acar and his colleagues \(2018\)](#) on the relationship between certain psychopathologies and creativity provided support for an inverted-U-shape relationship between the two. Runco admitted the interpretive nature of tension that makes it hard to generalize, and responded to Gardner with “more is not necessarily better”. According to him, even the optima may not be optimal at certain times. While some amount of asynchrony motivates, it may be inhibiting when it becomes excessive. Ideally, it is best when “the tension is distributed such that the individual is not overwhelmed by one experience, nor from accumulation of disturbance and depletion of resources” (p. 188). Briefly, the optimum level of asynchrony is the situation where individuals are challenged but can adapt and grow. According to Michael Rutter, the optima depend not only on the amount of tension but also on the way individuals react to it. The cognitive capacity of individuals determines how much tension with which they can successfully cope.

Such generalizations may fail in certain cases. Keith James found that originality is improved when people perceive conflicts in the domains on which they focus. Howard E. Gruber went further and argued that the association of tension with fields ranging from sciences to arts differs. He suggested that sciences are linked with interpersonal tension while arts are related to intrapersonal tension. As a result, there may be domain-dependency in the optimal level of tension. Csikszentmihalyi described the optimum level of asynchronicity between the person and the fields as follows: “The creative individual must reject the wisdom of the field, yet she must also incorporate its standards into a strict self-criticism. And for this one must learn to achieve the dialectical tension between involvement and detachment that is so characteristic of every creative person”.

The inverted-U-shape relationship between creativity and asynchronicity has been explained in several ways. According to Martindale, the optimal performance occurs at the moderate level of cortical arousal. James A. Easterbrook proposed that this relationship is mediated by task complexity: higher levels of arousal are efficient for simple tasks but not for complex tasks. Task performance decreases in low or high arousal levels compared to the optimal level because of the presence of irrelevant cues or lack of several cues, respectively. The optimal performance should be expected when individuals have several cues that can be used for a novel and original idea.

In a study on the comparison of the high versus low creative people with respect to anxiety and defense mechanisms employed, Ingegerd Carlsson found that the high-creative group had more anxiety than the low-creative group. She reported that mild and moderate signs of anxiety are found “almost exclusively” among the high-creative group as measured by meta-contrast technique. If we consider anxiety as a possible sign of asynchronicity at the personal non-cognitive level, those findings confirm an inverted-U-shape relationship between asynchronicity and creativity. An example of unproductive asynchronicity in organizations is intensified interpersonal conflicts. Although some level of conflict helps new ideas and syntheses to emerge, too much conflict undermines a positive working environment, resulting in rumors, gossip, and destructive competition.

Asynchronicity in Practice

Education

If asynchronicity is essential for creativity, can we create asynchrony to stimulate and enhance creativity? According to Piaget, children do not show interest in any stimuli if it is far above their cognitive level or when it is a routine task. The ideal situation is the presentation of stimuli that is somewhat challenging but graspable for a child. This level of discrepancy was contended by Lev S. Vygotsky (1978), who introduced the concept of the *zone of proximal development*, defined as “the distance between the actual developmental level as determined by independent problem solving and the level of potential development as determined through problem solving under adult guidance, or in collaboration with more capable peers” (p. 86). Creative potential of children can be maximized through challenges that fall within the zone of proximal development. According to Runco and Radio, one critical factor for parents and teachers is their recognition of creativity in children because providing environments that support creativity is only possible if they believe that the children possess it at some level. Once they have a realistic perspective about the creativity of their children, they can regulate their expectations. They described this as *scaffolding*.

Apparently, the view of asynchronicity has solid bases in education. Contrary to frequently suggested approaches such as unconditional positive regard, which refers to acceptance of the ideas without any critiques, asynchronicity offers to confront the individual with the defects and drawbacks of the creative products and encourages showing some ways to improve creativity at the creator's pace. However, it may become unproductive depending on the children's perceptions. Instructional activities can be designed in a way that students experience tension. Teachers can point out, for example, the gaps and incomplete parts of the ideas and theories instead of merely providing the facts. According to E. Paul Torrance, tension is aroused when we sense the incompleteness or disharmony. This tension lasts until we come up with explanations or solutions resulting from long-lasting processes of trial-error, manipulation, guessing and testing. Having students notice and recognize the disharmony and incompleteness can be intriguing and curiosity-provoking.

Organizations

Asynchronicities are useful for organizational creativity, too. Indeed, Michael A. West argued that innovation and conflict are concomitant: “If a new way of doing things is introduced within an organization and no conflict is generated (that is, there are no disagreements about the content or process of the innovation), or if there is no resistance by organization members to the innovation, then this innovation is not really new nor does it offer a significant contribution to the organization. Innovations threaten the status quo and thereby produces conflict (p. 101)”

Various benefits of conflict and asynchronies have been found in studies of organizations and the workplaces. Lorraine Dugotino suggested that brainstorming techniques should be designed to yield ideational conflicts because creative ideas arise from the conflict and confusion. Victor A. Thompson complained about the conditions within a bureaucracy led by monocratic social structure. Driven by the purposes of productivity and control, those conditions do not contribute to creativity and should be changed. He suggested a looser, decentralized and evolving structure, which allows freer communications, rotation of assignments, modification of the incentive system, and changes in management practices. Empirical studies support the role of conflict in organizational creativity. Keith James and his colleagues found that conflict can enhance or hinder creativity depending on the situation and individual. Perceived conflict improved creativity on tasks that match an individual's orientation and reduced it for tasks outside of that orientation.

Objective Assessment of Asynchronicity

As Gardner and Wolf acknowledged, finding asynchronicities is not difficult. That can make the concept more elusive and subjective for scientific study. As a matter of fact, even with the benefits noted above, there is no objective way of assessing both asynchronicities and synchronicities. The lack of empirical research on asynchronicity is a corollary of the absence of objective criteria. However, some special methods of measuring creativity are based on ideas similar to asynchronicity. One such example is the Chiara S. Haller and Delphine S. Courvoisiers approach to personality tests as an indicator of asynchronicity given the premise that the response pattern of creative people is complex. Complexity of the responses stems from the presence of contradictory traits in their personalities. They hypothesized that creative individuals will be inconsistent in their responses to test items, choosing contradictory poles. Therefore, we would see more variability in the responses of creative people than in those of non-creative people. They tested this hypothesis by comparing students from art and psychology majors. They found that complexity in conscientiousness was greater among visual art students than music and psychology students, and visual art students show greater overall complexity than psychology students.

Preference for oscillating between contradictory poles was the basic principle of a new scoring method for divergent thinking tasks that Selcuk Acar and Mark A. Runco (2015) developed based on the theory of complex personality. They identified 11 dimensions that can be objectively identified in the responses to the divergent thinking tests. Another idea that is consistent with asynchronicity is to measure creativity based on the hypothesis that creative people prefer asymmetry over symmetry. The Barron Welsh Art Scale is an example of this kind. The scoring was based on whether participants like or dislike the stimuli, some which are either symmetric or asymmetric. The underlying idea is that creative artists prefer asymmetric, irregular, or even chaotic figures.

John C. Rosen found that this test discriminated artists from non-artists, while scores were not significantly different between art students and established artists. Further attempts to clarify the definitional scope and objective assessment of asynchronicities would stimulate studies of the role of asynchrony in creativity.

Conclusion

Asynchronicities are many in the lives of creative people and can be classified into three groups—personal, impersonal and multi-personal, or two groups—interpersonal and intrapersonal. The view of asynchronicity provides a unique perspective in understanding creativity, and the wide range of asynchronicities complies with the recent conceptualizations of creativity as “syndrome”. A certain level of asynchronicity seems to be helpful for creativity, but too much may be counterproductive. A critical issue regarding asynchronicity research is the difficulty in assessing it as we lack objective measures. Asynchronicity also challenges the view of person-environment fit, which asserts that a synchrony between the person and environment is favorable for creativity. Further studies are needed to resolve that controversy.

Introduction to Attention

Everyone knows what attention is. It is the taking possession by the mind...of one out of what seem several simultaneously possible objects or trains of thought.....it implies withdrawal from some things in order to deal effectively with others

This quote from the eminent American philosopher and psychologist William James (1842–1910) elegantly illustrates his view on attention. In his influential book “The Principles of Psychology”, he proposed that the mind is a continuous stream of thought and that attention helps us “pick” from this stream. One of the earliest formalized models of attention was proposed by Broadbent in 1958. This model offers a metaphor for attention as a filter, which selects certain stimuli for further processing while filtering out irrelevant information. This theory was later revised by Treisman, who addressed the short-comings of the original. Since then, other models of attention have been proposed, however the original frameworks still remain influential. Regardless of the theory, it is generally assumed that selection of key information at the exclusion of others (or selective attention) is necessary, since cognitive resources are limited in capacity. Shifts in attention can be driven by external events and also be under internal, voluntary control. Since creativity, like most other aspects of cognition, involves selection of some information at the exclusion of other information, it may be natural to question how creativity is associated with attention and indeed this is a topic that has been enthusiastically pursued in research.

Two of the most prominent theories linking attention and creativity include defocused attention and flexible attention—the ability to switch between the focused and defocused modes of attention. This chapter discusses each of these theoretical perspectives in detail, together with the associated evidence. It also reviews exciting research linking attention and creativity, including the effect of mindfulness on creativity and research in people with Attention Deficit Hyperactivity Disorder (ADHD). Following this, theoretical concepts aiming to bring these conflicting views together are discussed, as well as suggestions for future research.

Many studies discussed in this chapter used standardized measures of creativity, which can be classified under two broad categories: tests of divergent thinking and tests of convergent thinking. Divergent thinking generally involves providing solutions to an open-ended problem, to which multiple correct answers are possible (e.g. an alternative uses task asks to provide unusual uses for common objects). Convergent thinking, on the other hand, involves drawing on existing knowledge to arrive at a solution to a specific problem with constrained parameters where only one correct answer is possible (e.g. the Remote Associates Test asks to find a common associate linking three otherwise unrelated, words).

Defocused Attention

In the 1960s, Mednick proposed that creative people are able to connect distant ideas and concepts to arrive at creative ideas and solutions. It has also been suggested that a wider, or defocused, breadth of attention allows creative people to pay attention to information that others may find irrelevant. As a result, they are able to connect previously unrelated concepts to arrive at creative solutions, more so than people who have a focused breadth of attention and only pay attention to information that is relevant to the task at hand. Defocused attention has also been described as “over-inclusive thinking”, and “leaky”, or “diffuse” attention. The defocused attention view of creativity has been supported by findings indicating that people high in creativity are better able to utilize incidental or irrelevant information using experimental tasks. One of the earliest examples of such a task comes from the 1970s by Dykes and McGhie. In their study, participants listened to words played through headphones. Importantly, different words were presented to each ear and participants were asked to attend to the words played in one ear and ignore the information heard in the other. Participants who scored high on a creativity-related measure remembered more words from the irrelevant ear in

a subsequent recognition test than participants scoring low on the creativity-related measure. This link has also been demonstrated using self-report. For example, [Kasof \(1997\)](#) found that creativity was correlated with a self-report measure of breadth of attention. More recent findings also indicate that performance on creativity tasks such as the Remote Associates Test (RAT) is significantly related to participants' use of incidental information.

Another strand of evidence for the defocused attention view of creativity comes from studies on latent inhibition. A latent inhibition task involves presenting a stimulus (e.g. tone, light, or background color), which is later made to signal an event (e.g. onset of a picture on the screen). Generally, people learn to ignore the pre-exposed stimulus as it is considered irrelevant; there is a delay in learning this association compared to that involving a stimulus which was not pre-exposed. This is referred to as the latent inhibition effect. People who score high on creativity measures, however, tend to have a smaller latent inhibition effect—it takes them less time to learn the association involving the pre-exposed stimulus. Evidence from latent inhibition studies demonstrates that creative people are more likely to pay attention to previously irrelevant stimuli, although there is some evidence that this may depend on the exact types of tasks and measures used ([Zaksaitė et al., 2017](#)).

An interesting approach to studying the influence of defocused attention on creativity has been used by Jarosz and colleagues. They asked participants to solve RAT problems while under the influence of alcohol. They found that alcohol consumption increased the number of RAT problems which were solved; the time taken to solve these problems was also faster. They suggested that the reason for these findings is that alcohol results in decreased attentional control, providing further evidence for the role of defocused attention in creativity.

It has also been proposed that positive mood broadens attention. A study by Rowe and colleagues in 2007 found that people were more susceptible to distraction in an RAT task after a positive mood was induced. All these strands of evidence indicate support for the link between defocused attention and creativity. Next, we discuss two further contexts which are useful for demonstrating the link between creativity and defocused attention—mindfulness and ADHD.

Mindfulness

Mindfulness practices involve manipulation of attention in order to focus on the present moment making it a fascinating context to study the link between attention and creativity. It has received significant interest from the wider scientific community in the past decade. Although the concept of mindfulness and its practices are highly varied, it can be classified into two main types: Focused Attention (FA) and Open Monitoring (OM). The FA practice involves focusing on an “anchor”, usually natural breath, to bring attention to a particular point on the body. Other commonly used anchors are physical objects, thoughts, or sounds around the practitioners. In contrast, the OM practice encourages individuals to “set the mind free”, allowing any thought or emotion to arise without judgment. Because FA practice involves focusing attention, we may expect it to promote a focused attentional state, while the OM practice may be expected to promote a defocused attentional state.

Studies have successfully demonstrated that practicing mindfulness is linked with reduced stress, enhanced positive feelings, reduced anxiety, and increased pain tolerance. However, in recent years interest has moved beyond investigating mindfulness as a mere well-being tool. For example, studies have shown that mindfulness training enhances the ability to use attention efficiently. There are also numerous examples of artists who practice mindfulness to support their creative process. In their book “Wired to Create”, authors Kaufmann and Gregoire quote a number of creative people who acknowledged the importance of mindfulness in their creativity. For instance, Steve Jobs, the co-founder of Apple Inc. and the mind behind the highly successful iPhone, said that meditation was the main source of his creativity. Given this anecdotal and scientific evidence, it has been predicted that a link between mindfulness practice and creativity may also exist, with mindfulness exerting a positive effect on creativity.

In 2012, a group of scientists ([Colzato et al., 2012](#)) investigated the possible impact of mindfulness based on FA and OM on divergent and convergent thinking. They asked practitioners of both FA and OM techniques to take part in their study. After each mindfulness session practitioners also completed the alternative uses task and a short version of the RAT. This study showed that scores on the alternative uses task were higher for all participants after the OM sessions but not after the FA sessions. On the other hand, performance on the RAT was unaffected by either technique. The authors reasoned that the OM sessions, by encouraging participants to pay attention, and be open to any arising thought or emotion, induced a distributed attentional state. However, they also suggested a possible role of mood in explaining their findings and called for further investigation.

It is important to note that there have also been studies which did not demonstrate a link between mindfulness and creativity. These conflicting results were attributed to (i) a range of different creativity tests used, (ii) a range of mindfulness practices used and (iii) the multifaceted nature of both mindfulness and creativity. For instance, Domino published a study in 1977 with four groups of people. One group was enrolled in a meditation program, the second in a relaxation program, the third group was enrolled in a psychology course focused on enhancing creativity, and the fourth group underwent no special treatment. All four groups were given a battery of five creativity-related tests both pre and post treatment. Among these tests were the RAT and the adjective checklist. This study found that only the third group showed significant increase in creativity performance thus finding no enhancing effects of mindfulness on creativity. Importantly however, this study and others which failed to find the effects of mindfulness on creativity used a type of meditation that was similar to FA mindfulness practice, while Colzato et al.'s results suggest that it is the OM practices that are related to creativity. Based on Colzato et al.'s results, it may also be expected that mindfulness has stronger effects on divergent thinking, rather than convergent thinking performance.

More recently, [Baas et al. \(2014\)](#) conducted a series of studies to systematically disentangle the effects of FA and different facets of OM mindfulness practices on creative performance. In the first of these studies, they measured participants' ability to “act with full

awareness” with a measurement tool called Mindful attention awareness scale (MAAS). “Acting with full awareness” is similar to the FA practice; it is the ability to “fully engage in current activities with undivided attention, or focus on one thing at a time with full awareness”. People were encouraged to voluntarily direct and sustain their attention on a selected anchor (such as breath). Mind wandering, bodily sensations, and thoughts were closely monitored, and once people were aware of these, they were encouraged to disengage from these distractions and bring their attention back to the anchor (akin to focused attention). Participants also completed a divergent thinking task; they were asked to provide as many creative ways to use a brick as possible. Their study demonstrated that FA practice was linked with lower scores on this creativity-related task. Their second study looked at other components of meditation namely *observation*, *description*, and *acceptance without judgment*. *Observation* is similar to the open monitoring practice used by Colzato et al. (2012); it is the ability to attend to various stimuli and may be assumed to promote a defocused attentional state. *Description* is the ability of a person to verbally describe observed phenomenon without an evaluation. This entails actively labeling the thoughts and emotions as they arise. Finally, *acceptance without judgment* practice is the ability to be non-evaluative about the experience of the present moment. An example of this would be the ability to refrain from evaluative labels such as “good” or “bad”, as related to thoughts and emotions. In this study, creativity was assessed using a creative achievement questionnaire, a questionnaire asking about their ability to come-up with creative ideas, and through a divergent thinking task asking the participants to provide unusual uses for a rope and a tin can. This study showed that *observation* was associated with enhanced creativity: it led to significantly enhanced originality and flexibility in ideas, creative achievement, and self-reports of creativity. On the other hand, *description* and *acceptance without judgment* practices only predicted flexibility in ideas; they were not associated with any other creativity-related measure. A final longitudinal study was conducted to establish whether open monitoring mindfulness practice leads to enhanced creative behavior. Participants completed an 8-week mindfulness course with a focus on enhancing observation practice. They were instructed to undertake independent meditation sessions every day for a period of 20–30 min in the mornings and evenings. Creativity was measured before and after the 8-week course by a creative behavior questionnaire in which participants reported the frequency with which they engage in creativity-related behaviors such as “I often come up with original solutions for problems”. This study found that mindfulness training with an emphasis on observation led to enhanced creative behavior in a group of randomly selected volunteers, relative to the other forms of training. These robust findings offer more conclusive evidence that mindfulness practices lead to enhanced creativity. This is generally attributed to open monitoring mindfulness practices promoting a defocused attentional state, though this still remains to be demonstrated experimentally.

Attention Deficit Hyperactivity Disorder

Another way to explore the links between attention and creativity is by studying atypical populations in which attention may be implicated. For example, ADHD is characterized by symptoms of hyperactivity, impulsiveness and importantly, inattentiveness. ADHD is often diagnosed in childhood, but the symptoms can continue into adulthood, with an estimated prevalence of 2.5% (Simon et al., 2009). While the exact nature of attentional symptoms in ADHD is still being investigated, studies have found that ADHD can result in difficulties with attention and a greater susceptibility to distraction. This suggests that people with ADHD may exhibit greater defocused attention. Considering the defocused attention view of creativity, it might be expected that people with ADHD would have greater creativity. Some studies have indeed found that people with ADHD perform better on certain creativity tasks. For example, White and Shah (2006) found that adults with ADHD scored higher on a divergent thinking task than adults with no ADHD, while adults with no ADHD performed better on the RAT. These findings have also been partly replicated in a follow-up study in which the authors found that people with ADHD had higher originality scores on a verbal divergent thinking measure, while their performance did not differ on figural divergent thinking measures. They also found that people with ADHD scored higher on self-reports of creative achievement.

A study conducted by Zabelina et al. (2014) looked at subclinical symptoms of ADHD and creativity-related measures. They found no association between scores on a self-report ADHD symptom scale and divergent thinking performance, but a positive relationship between scores on the ADHD scale and creative achievement. However, they also found that this link was moderated by academic achievement—when academic achievement was considered, the link between ADHD scale and creative achievement became non-significant. Interestingly, other studies have also found that intelligence is implicated in the ADHD–creativity link. Carson et al. (2003) suggested that intelligence may act as a moderator of the relationship between a particular psychological phenomenon and creativity. Certain psychological phenomena may be sub-optimal in the presence of intelligence levels below a certain threshold but become advantageous in the presence of high intelligence as this may afford further resources to compensate for any associated difficulties; this is known as the threshold theory. In their study, they investigated latent inhibition (propensity to ignore previously irrelevant information discussed in the previous section) and found that while latent inhibition was negatively related to creative achievement, this effect was moderated by intelligence. Furthermore, studies which have found superior divergent thinking performance in participants with ADHD have often used college-student samples, which would likely selectively oversample people with average or above average intelligence relative to the general population. Therefore, this could be one reason for the contradictory results regarding ADHD and divergent thinking, although note that the relationship between creativity and intelligence may not be as straight-forward as outlined by the threshold theory (e.g. Kim, 2005).

However, recent findings by Boot et al. (2017) raise a question about whether the relationship between ADHD and creativity-related measures is due to difficulties with attention. They found that it was the hyperactive/impulsive symptoms that seemed to be responsible for the relationships between ADHD-symptoms and creativity, rather than in attentional symptoms. In particular, hyperactive-impulsive symptoms were positively associated with self-reported creative achievement and divergent thinking, but

negatively related to performance on the RAT. In attentional symptoms were not related to any creativity indices. While these results may appear surprising, there may be a relatively straight-forward explanation for them. Impulsivity is associated with risk-taking behavior and creativity has been found to be related to risk-taking, particularly social risk taking (Tyagi et al., 2017). Therefore, while the link between creativity and ADHD has been shown, whether this link is due to broader attentional scope is less clear, suggesting the need for further investigation.

Flexible Attention

As outlined in the previous sections, there is a substantial body of literature supporting that defocused attention is important for creativity. Note however, that the importance of focused attention has also been acknowledged. Martindale (1995) was one of the first to formalize a theory which considered that both defocused and focused attentional states are important for creativity and each serves its own function in the creative process. His view was that creative people are better able to alternate between the two different states of attention: a free associative state which corresponds to defocused attention and a logical, goal-orientated state which corresponds to focused attention. He suggested that the former, defocused attention state, is important for linking previously distant concepts in order to come-up with creative ideas. The latter, focused attentional state, becomes important when the creative ideas have to be selected, elaborated, and refined. In this way creative people might have the ability to switch between focused and defocused modes of attention based on the demands of the task or situation at hand. This ability to switch between the different modes of attention is also referred to as flexible attention, cognitive control, or cognitive flexibility.

Support for Martindale's view of creativity comes from tasks which involve either high or low ambiguity and interference from irrelevant or distracting information. An example task of low ambiguity and interference would be a simple reaction time task involving responding as fast as possible to the appearance of a target. An example of a task with high ambiguity or interference would be the Stroop task, which involves looking at words of colors (e.g. "Red", "Blue"), which are printed in differently colored ink, e.g. the word "Blue" printed in green ink. To perform correctly, participants have to name the color of the ink while ignoring the written word. Generally, people perform poorer when the color of the ink is different from the color of the word e.g. the word "red" printed in blue ink, than when the color of the ink matches the written word e.g. the word "red" printed in red ink, indicating interference from the written word. Martindale and colleagues hypothesized that on tasks which involve low ambiguity or interference, creative participants would benefit from focused attention and they would have superior performance. However, on tasks which involve high ambiguity or interference, a defocused mode of attention would be used and creative participants would have lower performance. In a paper published in 2007, they investigated these predictions. To indicate creative potential, they used a composite measure of scores from an RAT task, an Alternative Uses Task, and the Creative Personality Scale. They used four reaction time tasks which involved either high or low interference. The findings were consistent with their predictions—participants who scored high on creative potential measures were faster at responding on the tasks which involved minimal interference, but slower on tasks which involved high interference. These results have been partly replicated in a follow-up study.

One further strand of evidence for the flexible attention view of creativity comes from studies looking at people's ability to switch between different perspectives. One example of such is a Navon letter identification task, which measures the ability to switch between local and global levels of information. This task involves presenting letters which are made of smaller letters. The global letter can be either the same as, or different from, the smaller letters (e.g. an H can be made-up of Hs or Ns, see Fig. 1). Participants are asked to pay attention to the local level while ignoring the global letter, or pay attention to the global level while ignoring the local letters and this varies across different blocks. There is some evidence to suggest that performance on the Navon task is related to performance on divergent thinking tasks: participants scoring higher on divergent thinking have been found to be faster at reporting the letters at the correct level.

A recent study by Radel et al. (2015) used an interesting method to investigate the link between divergent thinking and flexible attention. Generally, tasks investigating underpinnings of creativity-related outcomes use correlational approaches, which at times can be problematic (e.g. they are dependent on sample size, variations in the sample, and it is difficult to infer the direction of causality). In their study however, they used an experimental approach. Participants performed a task which required either high

or low levels of inhibition. The inhibition task was a visual-search task—participants had to respond to a target, while ignoring distractors. After performing this task, participants were asked to complete an alternative uses task. The authors reasoned that engaging in a task which requires sustained inhibition would deplete one's inhibitory resources and they would be less likely to engage in inhibition subsequently; this was also shown experimentally as participants' responses were worse on a task requiring inhibition after completing the demanding inhibition task. They found that after a demanding inhibitory task, originality and fluency scores on the alternative uses task were higher than after a less demanding inhibition task. These findings are consistent with the theory from Martindale and colleagues—they reasoned that higher creativity would result in poorer performance in tasks involving interference due to defocused attention. By definition, being more distracted by irrelevant information means that creative participants are worse at inhibiting or ignoring this information. Radel and colleagues' findings that lower inhibition (or greater depletion of inhibitory resources) resulted in better performance are consistent with this view, and may provide some evidence for the flexible attention view of creativity.

There have been several attempts to describe how the defocused, focused, and flexible attention views of creativity can be linked. For example, the dual pathway to creativity model proposes that creative ideas and products can be achieved through cognitive flexibility, cognitive persistence (which approximates focused attention), or a combination of both. The model assumes that different psychological phenomena which are associated with either cognitive flexibility or persistence would be positively associated with creativity and has received some support. Another example of bringing these perspectives together comes from Zabelina (2018) who proposed a "Model of Creativity and Attention". After reviewing the available behavioral and neurological evidence, she proposed that real-world creative achievement is associated with defocused attention, while flexible attentional control, or the ability to switch between the different modes of attention is important for performance on divergent thinking tasks, as it serves to inhibit the common, ordinary responses. Note that Zabelina's predictions seem somewhat contrary to Radel and colleagues' results—they found that lower inhibition was related to higher performance on a divergent thinking task, while Zabelina's model predicts that lower inhibition (of common responses) would be related to lower performance on a divergent thinking task. This suggests that further investigation may be needed to specify the mechanisms of how inhibition functions in creative participants and how this relates to flexible attention.

Overall, while there is evidence for the role of flexible attention in creativity, further work needs to be done to specify the mechanisms behind this link. Given the variety of measures used to indicate creative behavior, achievement, and potential, as well as numerous indices within a particular task (e.g. divergent thinking responses can be scored for originality, fluency, flexibility, and elaboration), it is possible that different types of attention may be related to different performance indices, as proposed by the promising, recent frameworks, though the exact nature of the mechanisms involved remains to be specified.

Conclusion

A rich array of research has linked creativity with defocused attention, including studies on latent inhibition, alcohol intoxication, mindfulness, Attention Deficit Hyperactivity Disorder, as well as studies on people's ability to use incidental information. These provide evidence that creativity involves the use of information that may be considered irrelevant. Creativity has also been linked with the ability to switch between the focused and defocused modes of attention, also referred to as flexible attention. Several theories and models have been proposed which attempt to unify these different strands of evidence. While they provide some elegant solutions, they may need further conceptualization to unify the existing results with theoretical predictions, and to qualify the seemingly complex relationship between creativity and inhibition. It is clear that while we know a lot more about the links between creativity and attention than we did a century ago, important questions still remain. In addition, further research is needed to clarify the link between different tasks and measurements related to creativity, perhaps using experimental methods.

Introduction

Creativity is a complex process and cannot be understood from just one perspective. It has predominantly been studied in terms of cognitive and personality processes, but recently situational forces have intrigued researchers. Attribution theory is a social psychology view which aims to understand the way people give reasons for and draw meaning from the others' behaviors. Attribution theory deals with people's responses to questions beginning with "Why?—Why people do the things they do?" If there is not an obvious answer for a behavior, then people tend to create their own explanations for this behavior.

Attribution theory was originally developed by Fritz Heider (1958) who is one of the most important social scientists of the 20th century. According to Heider, there are basically two explanations for behaviors—external causes or internal causes. Approximately 10 years after Heider's discussion on attribution theory, Harold Kelley extended it. According to Kelley, attribution theory analyzes cause and effect relations. It can be related to every area of psychology that involves judgment, perception, and thinking. Given the importance of environment is clearly indicated in the seminal frameworks of creativity (i.e. role of four Ps—person, press, process, and product) application of attribution theory to creativity is not surprising. Attribution theory was first applied to creativity in a very detailed article by Joseph Kasof (1995) in a special issue of the *Creativity Research Journal*. That Featured article was followed by a series of Commentaries. In this chapter, I will discuss the attribution theory and the reactions of creativity researchers, including those of the CRJ Commentators.

Background and Basic Concepts

Creativity has both objective and subjective aspects. As often defined, creative products must be original, novel, and infrequent. This is the objective approach to creativity assessment and constitutes the main dimensions of many creativity tests. Objective assessments of creativity are based on normative criteria. One of the main advantages of objective creativity tests is the evaluation of creative products by blind judges. This yields high inter-rater reliability. However, from a subjective view, use of objective criteria seems to fall behind measuring creativity since creativity does not emerge in isolation. Creative products must also be approved or accepted by the "judges," and this is the subjective approach to creativity assessment because judges may vary in their perceptions and evaluations of a creative idea, solution or product. Kasof argued that objective tests ignore the subjective aspect of creativity by explaining all the variation in creative performance through individual differences. He claimed that objective tests tend to reduce ecological validity. Overreliance on objective tests discards the point that reception of original products is socially constructed.

When we consider the creativity as a "social construct," just as with evaluation of physical attractiveness, judgments of creativity also depend on social values. All judges have their own values, which influence their evaluations of the products. Judges—who may

be scientists or experts but also laypeople—are the persons that decide whether a product should be approved, accepted, and valued. In “uncontrolled” real life settings, creativity is more about social judgment. In this view, even if the individual creativity is assessed, it cannot be thoroughly isolated from the social environment.

In a nutshell, attribution theory underlines *situational factors* and challenges the conventional theories of creativity which used to focus on *dispositional factors*.

Dispositional Versus Situational Factors

If the explanations of a behavior come from within the individual, this is called dispositional cause. Throughout the centuries, both researchers and laypeople have attributed creativity mostly to genes, brains, personal traits, and so on. For instance, Plato defined creativity as an inspiration, a kind of madness. According to Aristotle, the creative process is the product of natural laws; in other words, creativity comes from something that exists naturally. Kant also saw creativity as the kind of genius. He emphasized the unprecedented, spontaneous nature of the creative process. Galton, one of the most eminent scientists of the 19th century, extended Darwin’s theory to creativity and defined creativity as an inherited ability.

In academia, creativity has been the subject of cognitive and personality psychologists rather than sociologists or social psychologists. Creativity first appeared as a concept in psychology literature in Joy Paul Guilford’s Presidential Address, which focused on dispositional causes. This tradition has become the mainstream with the contributions of E. Paul Torrance, Frank Barron, Mark A. Runco and many others. This situation is not different for laypeople. According to most of the people, creativity is a quality of persons and a personality trait. Thus, people either have it or not, and most people do not have it. Laypeople mostly do not think that creativity can be a continuum and all people can have it to some amount. This dichotomizing view could be a result of the overall tendency of the field to examine the personal differences between creative and noncreative individuals.

During the past 20 years, in addition to Kasof, Teresa Amabile, Mihaly Csikszentmihalyi, Beth Hennessey, Keith Sawyer, Dean Keith Simonton, and other researchers have focused on situational factors as well as dispositional ones. According to those researchers, creativity is not only a product of an individual effort but also a product of complex social systems. Their research indicated the influence of rewards and external motives, field and domain, and political situations and zeitgeist on creativity. Kasof did not negate the relationship between dispositional characteristics and creativity. However, he doubted the direction of the relationship between dispositional characteristics. Contrary to the common assumption, such characteristics can be the results rather than the causes of creativity.

According to Amabile (1982), experimental studies on social and environmental factors of creativity is not very common because of the lack of clear operational definitions and reliable assessment methods that fits the social psychological views of creativity. She offered consensual assessment technique as a creativity assessment methodology from a social psychological perspective. According to this technique, judges—observers, raters—in a field can decide if a product is creative or not. Like as the judgment of physical attractiveness, judgment of creativity depends on the social context.

According to systems model of Csikszentmihalyi (1999), in order to understand creativity, we need to look at it from a broad perspective, as a social and cultural production. What is creative and what is not depends on the reasonable changes in the culture, so it is important integrate individual experiences with social perspectives of creativity. What makes a product creative is not only the individual quality of the product, but more importantly, if it recognizes as creative by others. Fields of creativity is one of the three key concepts of systems model and members of the field decide what is novel, or creative, in a domain. For instance, evaluation of the Van Gogh’s paintings changed later because the field change its criteria. If the members of this field did not change their criteria for creativity, those paintings would be never recognized as creative and, most probably, forgotten.

Factors Leading to Attributional Bias

When people try to explain other’s (or their own) behaviors, several factors cause attributional biases. The following sections will address these factors.

Covariation Principle

Covariation principle was introduced by Harold Kelley who defined it as attribution of an effect to one of its potential causes with which it covaries over a period time. Something might be the cause of an event, if it present when the event occurs and not present when the event does not. Covariation principle applies to the situations in which the attributors observed or noticed the effect two or more times. Accordingly, shifts from one kind of behavior to another yield different attributions for different reactions to this behavior. A famous example, known as the prisoner’s dilemma, indicated that people’s attributions regarding the same behavior pattern of a person can differ depending on the response of the reactant. In one case, a group of people observed two people, one of whom behaved cooperatively and the other also reacted cooperatively. When the first person, in turn, behaved competitively, most of the judges believed that first person was competitive. In the other case, the actions of the first person were the same (cooperative and competitive, respectively) while the reaction was competitive in the second case. A smaller size of the observers believed the first person was competitive. The attribution of being “competitive” about the first person is higher when the response of the second person is cooperative than when the response is competitive.

Three type of covariation information is useful to make attributions: consensus, distinctiveness, and consistency. *Consensus* refers to generalization across persons. When people make attributions, they tend to consider whether all individuals behave similarly in

a given situation. *Consistency* is generalization across time. People often consider if a person behaves similarly in other similar situations. *Distinctiveness* is generalization across situations. It explains if a person behaves similarly in different situations. People can know that their judgments are true if the judgment is associated distinctively with the stimulus (distinctiveness), if the judgment is similar to the judgments of other people (consensus) and if the judgment is consistent over time (consistency).

These three criteria are vital for attribution validity; however, according to Kasof (1995) they are not equally important. Consensus is more important for attributions of creative behavior than consistency and distinctiveness. The most important characteristic of creative behavior is originality and there is a negative correlation between originality and consensus. If the originality of a creative product increases, its consensus value decreases, and lower values for consensus cause higher internal attributions. Thus, highly creative behaviors are attributed to more internal causes than fewer creative behaviors. On the other hand, noncreative behaviors are attributed to dispositional factors only if the situation strongly supports the creativity.

Influence of number of creators on attributions may be a good example for the *covariation principle* in terms of *consensus*. The greater the number of creators, the higher the consensus and the more likely it is to be attributed to an external cause. Thus, when two or more scientists work on the same product independently, the consensus is higher than when it is made by only one scientist. Multiple creations are attributed less internally than single creations. In addition, if the multiple creators report the same creation at nearly the same time, the consensus will be higher, so the creation is attributed to more external causes. If two or more creators work on the same product at the same time, consensus is again higher than for single creations, so the creativity is attributed to external causes.

For consistency, if people behave creatively in a given situation over and over, their creativity is mostly attributed to dispositional causes. On the other hand, inconsistent creative products are attributed to situational factors, such as having a supportive boss for that time. If the creative product is not consistent, the creator has less of a chance to become well-known even if the product is really good and valuable. As a result, those with longer careers have more of a chance to become well-known because they have more opportunities to produce creative products than those with shorter careers.

Although distinctiveness is not as important as consensus, it still influences the attributions of creativity. If people are creative in all situations, distinctiveness is lower, so the behavior is attributed internally. But if the creative behavior is common in one situation and rare in other situations, the creativity is attributed to external causes. If a person is creative in different domains, distinctiveness is lower; therefore, creativity is mostly attributed to internal causes. Hence, if two creators create the same number of products, but one's products are in different domains, he or she is considered more creative than the other. Even within a domain, if people use different styles, materials, etc., they are considered more creative than others who use the same styles or same materials. Having information about consistency and distinctiveness affects people's explanations about creativity. Most of the time, however, attributions are made without information about consistency and distinctiveness.

The relationship between these three variables results in different kinds of attributions. Lower levels of consensus and distinctiveness yield internal attributions whereas higher levels for consensus and distinctiveness result in external attributions. Higher levels of consistency tend to lead to more stable attributions. More discrepant levels of consensus and distinctiveness (i.e., higher for one and lower one other) induce more complex attributions.

Salience

Salience plays an important role in the attributions of creativity. For example, think about the music group you like most. Who might be the most creative person in the group? Most people would answer, "The lead singer." Because singers are more salient than guitarists, bass players or drummers, people perceive them as more creative than the other members of the group. If a poet appears on a TV show, people think that he or she is more creative than other poets who rarely show up on TV.

Salience can operate in other ways, too. For instance, "wishing to be alone" is seen as a characteristic of creative persons. Creative persons are considered unsociable, alone and marginal ones, or unsociable, alone and marginal people are considered more creative than others. In a group, if a person has an unusual hair style or color, wears different from others and behave marginally, observers are more likely to believe that he or she is more creative than the other members of the group even if there is not any evidence to support this assumption.

Salience is also related to the number of creators especially in scientific creativity. Scientific work has become more collaborative; therefore, attribution of scientific creativity to internal causes has decreased. However, while experimental studies are often done by multiple creators, theorists usually work alone. Therefore, theoretical studies are still attributed mostly to internal causes. Similarly, collaborative studies are more common in science than in humanities, so creativity in humanities is mostly attributed to internal causes in contrast to creativity in science.

The relationship between creativity and salience is bidirectional. Creative products can also lead to salience because creative things are novel, and novel things are usually more salient. People tend to see salient products as a result of the personality of the creators and underestimate the impact of situations. However, there is an observer versus actor difference in salience. When an individual observes another individual in a situation, the observer perceives the actor as more salient than the situation, but the actor perceives the situation in which he or she is in as more salient than himself or herself. Thus, the observer attributes the behavior more to dispositions than the actor. Of course, this can be since creators experience the process, but observers can only see the product. This tendency of observers is known as *fundamental attribution error* which refers to the tendency of the observers to overestimate the dispositional factors and to underestimate the situational factors. It occurs more commonly for creative behaviors than any other behaviors because creative behaviors are more novel and original, so they are more salient than other behaviors.

The relationship between salience and creativity can also be seen in minority groups. Attributing creativity to people from minority groups is also common since they are highly salient. Therefore, creative people of minority groups are perceived as more talented than their actual performance, not just because of their creativity but also because of their rareness. According to Kelley, who introduced the *augmenting principle*, if both inhibitive and facilitative factors of a behavior are present together, the greater causal weight is given to the facilitative ones. For instance, psychopathologies or physical handicaps yield salience which might attract researchers' and lay people's attention more than others. There is a positive bias for schizophrenics in the creativity literature. However, a meta-analytic review with the analyses of 42 studies revealed that there is a negative correlation between chronic schizophrenia and creativity (Acar et al., 2018).

Stereotypic definitions of creative personalities can also be influenced by the salience effect. When we ask about the personality traits of creative individuals, lay people often describe them as nonconformists, independent, risk-takers, unsocial, and so on. On the other hand, it has been argued that creative people possess more complex personalities whereas people tend to notice the rarely observed and salient aspects. As a matter of fact, Mihaly Csikszentmihalyi, W. Ed McMullan, Frank Barron and others defined the most obvious characteristic of creative people as their complex personality. According to these researchers, creative people can bring together all the possible characteristics of humankind in themselves at the same time without any inner conflict. Nonconformity, independence and risk-taking are also characteristics of creative people, but they are exaggerated beyond reality.

Self-serving Bias

One of the main concerns of attribution theory is people's judgments about their own abilities, feelings, achievements etc. People usually attribute desirable outcomes to their personality traits and undesirable outcomes to environmental factors. For instance, reasons for acceptance, rejection or revision of the articles by journals were asked to 230 authors. They mostly attributed acceptance to internal causes but rejection and revision to external causes (Wiley et al., 1979).

Creativity, as a desirable characteristic, is also mostly attributed to internal causes. In a study, Brown and Rogers (1991) administered Remote Associates Test to a group of undergraduate students. However, half of the students received an easier version of the test than the other students. Of the students who received the easier version, and thus got higher scores than the other group, more believed that the test was fair and objective than did the students who received the harder version and got lower scores as a result. Studies showed that self-serving bias rules in brainstorming activities as well. People tend to attribute others' original ideas in the group to themselves (Stroebe, Diehl, and Abakoumkin, 1992).

Like self-serving bias at the individual level, groups can also take credit for their successes, and attribute failures to external causes. This is called "group-serving bias". Especially in the environments where team work is more important than individual effort, the locus of attribution shifts from individuals to groups. In other words, people try to explain success and failures of the group instead of their own success and failures. For instance, when a football team wins a game, they attribute success to their group cohesiveness, but if they lose, they attribute failure to external causes such as unfair referee.

Group-serving bias can influence judges' evaluation. Judges usually evaluate the products of members of their own group as more highly creative than the products of members of other groups. This bias occurs when the group members are in or out of their own environment during the evaluation period. For instance, products created by members of one's own sex are evaluated as more creative than those created by members of the other sex. People from the same nationality evaluate each others' products more highly than the products of others. Kasof exemplified Adolf Hitler who believed that all of the technological, artistic and scientific inventions in history were created by Aryan-Germanic people. Corollary to that, if people from other nationalities claimed that they created something, they just stole it from the Aryans, according to Hitler. Also, if a product says negative things about a group, the members of the criticized group evaluate the product as less creative even if it is evaluated as highly creative by experts.

Further Elaborations

There are other factors that can manipulate our attributions. They are general characteristics, status generalization, and social loafing.

General Characteristics

General status characteristics such as gender, race, age, physical attractiveness or socioeconomic status affect performance expectations for a group of people. A high level of competence is expected from people with certain characteristics even if there is no previous evidence for the relationship between the specific characteristics and task performance. According to Proudfoot et al. (2015) experiments, there is a gender bias in the attribution of creativity. Creativity is associated with mainly masculine characteristics (such as self-reliance) rather than feminine ones (such as supportiveness). Moreover, if they create identical products, men were attributed more creative than women and supervisors evaluated female executives less creative than males.

Although researchers, such as James Kaufman and Kyung Hee Kim, offered measurement of creativity as a solution for cultural bias in assessment, there is still some racial bias in attribution of creativity. Mark Paul Frederickson (1993) examined the racial bias in design school juries in architecture, interior design, and several studio arts across three US design schools. Among all 112 juries in those three schools, there is only one minority jury member, who is a male Hispanic American. In addition, Hispanic American students and African American students were also underrepresented in those design schools.

Another attributional bias in dying young. If a successful creator dies at an early age, he or she becomes more eminent in the future. This is mostly because people remember them at their most attractive ages. Eminent people, like all of us, lose their physical attractiveness and popularity as they become older. Thus, if they die before their success wanes, people remember them as more creative, not because they are really more creative but because people always remember them with their most attractive appearance and most popular products.

Status Generalization

When people come together to achieve a goal, their out-of-group status also affects their inner-group status. In other words, individuals with high social status have advantages in a wide range of areas, even if there is no evidence that such advantages are deserved. High social status is associated with general expectations of talent. Hence, usually the people who are famous out of the group are assumed to be more creative in the group as well. For instance, if a scientist in a group has won a Nobel Prize, it is assumed that this scientist contributed the most to the group, or in a multi-writer article the contribution of the famous scientist is assumed to be higher than that of a PhD student.

A status-based bias is known as the *third-party status effect*. If the judges know that other people evaluate a product as creative, their probability of evaluating the product as creative is high. How other judges approve of creations influences one's evaluation of the product. However, the third-party status effect has been demonstrated only with domain-specific status characteristics. High status judges are more effective than low-status judges.

Social Loafing

When people work in a group and the individual effort is not identified, people exert less effort than when individuals act alone. This is called *social loafing*, and it affects the attributions. Groups who attribute their creativity to the unique contributions of each individual create more divergent ideas than groups who attribute success to the group as a whole. Attributing creativity to the whole group rather than each individual sends a subtle message that each individual's contributions are not identifiable. When people think that their contributions are not identifiable, they exert less effort to create new things. If people think that they will be held individually accountable, they will be more willing to see the issues from different perspectives. Of course, if groups are not willing to search beyond the obvious ideas, they create less divergent ideas. Hence, it is a common finding that groups generate fewer creative ideas than individuals.

Groups' lowered performance in producing creative ideas can result from conformity pressure. Group focus attributions may increase conformity pressure. When people work in a group, they mostly ignore their own ideas and try to adopt the majority's opinion because groups have a tendency to reject members who do not fit. Thus, individuals can avoid from introducing their original ideas. Consequently, groups tend to see issues from only one or two perspectives and come up with less divergent ideas.

Like creators, judges are also influenced by the norms and values of their groups. Group norms have obvious influences on people's behaviors including how people recognize creativity. Csikszentmihalyi stated that creativity can only be understood in light of social norms and values. Although creative products should somewhat deviate from the norms, according to Mark A. Runco, if they are much ahead of their time, they might not be recognized as creative in their time. Some of the most famous writers or artists were not recognized during their lifetimes, but they became eminent posthumously. Due to the deviation of their products from their time, no attention was given to them. Hence, the norms and values of the era is one of the most important determinants of people's judgments about creative products.

But group norms and values do not influence everyone to the same extent. The level of being affected from the society is determined by individual's relationship with the group. As their personal identities, people also have social identities which internalize values and norms. If the group is important and meaningful for a group member and social identity is more salient than the individual identity, group norms and values become the primary source of the given member's judgments, and members confirm the judgments of the group. But if the judges' personal identities are more salient than their social identities, they can easily express their own judgments in the group.

The influence of social loafing is more visible when the creative products are judged by a group of judges. If judges know that they will be held individually responsible for their evaluations, their evaluations become more positive than when they know that the evaluations are pooled.

Criticism of the Attribution Theory

Creativity researchers have evaluated attribution theory in different ways. According to Teresa Amabile, attribution theory indicates some ways to develop more comprehensive work-related or school-related creativity enhancement programs. Most creative training programs aim to improve personal traits (such as creative thinking strategies), but with the help of an attribution theory perspective, creativity enhancement programs can also focus on the facilitative and detrimental effects of environments on creativity and can aim to improve environments to help creativity. On the other hand, Amabile criticized attribution theory for its claim that creators notice the environment when the environment prevents their creativity but attribute all success to their personality when the

environment assists their creativity. Amabile's and her other colleagues' findings, however, indicated that people mention environmental factors as much as personal factors, a fact which attribution theory overlooks.

Mark A. Runco was the most critical of attribution theory. He objected to attribution theory for several reasons. First, it does not explain what creativity is; instead, it explains individuals' reactions to the creative products. Judgments can be biased. If they are not true, this does not mean that the product is not creative; instead it can be creative but not recognized. Second, having a creative idea, sharing it with others and convincing others are all different things. Thus, there must be a distinction between inherent creativity and attributed creativity. Attributed creativity is important for reputation because reputations are estimated by others' judgments. But reputation is not creativity, and people's judgments cannot explain inherent creativity alone. Third, attribution theory can explain the creativity of eminent people, but it ignores the daily creativity, known as *little c*. People who are creative in their daily lives but not eminent can sometimes remain unrecognized. Of course, this does not mean that these people are not creative just because they are not reputable. Furthermore, reputations can also be biased. For instance, some highly reputable people may gain people's attention, not because of the creative value of their current work, but because of the influence of their previous work. The ability to communicate and convince others is not a good predictor of the ability to generate creative ideas. Fourth, attribution theory can be applied to creative products and performance, but not to creative processes and potentials. Therefore, according to Runco, attribution theory does not seem to be a resourceful perspective for creativity.

Another criticism for attribution theory is related to cultural differences. Several studies discussed that fundamental attribution error is a "Western Bias" and there are differences between the Western and Eastern attributions. Culture can influence the way people think, behave and interpret the world around them. Thus, people all around the world do not interpret the human behaviors, including creativity, in the same way. According to Miller (1984), people from individualistic societies make more personal attributions, however people from collectivist societies make more situational attributions. Takahiko Masuda et al. (2008) examined the arts that created in different cultures. Western artists highlight mostly individual people and objects in their works. However, Eastern artists draw more space to background and scenery. These cultural differences in art works were seen in both professional artists' and schoolchildren's works. In another study, Paletz et al. (2011) compared the attributions of different cultures in implicit theories of creativity. They asked the Japanese and American (Asian Americans and Caucasians) participants to list as many words for creative behaviors and traits associated with creative people. Results showed that Japanese listed more external and fewer internal creative activities and personal traits.

According to Robert J. Sternberg, dispositional versus situational views of attribution theory cannot be adaptable for creativity studies. He claims that creativity and the attributions of creativity are two different concepts and perspectives on attribution of creativity cannot be used to understand the theory of creativity. If we want to understand creativity, we need to look at both internal factors that lead to creativity and external factors that lead to attributions of creativity.

Michael M. Mumford criticized the attribution of creativity from a different perspective. He does not reject the importance of nonverbal cues, such as dress and gestures, on attributions. However, these cues cause attributions only if there is no evidence of performance or the judges lack expertise in the field. If there is enough information for the performance, judges focus on the objective outcomes rather than the subjective attributions and make evaluations accordingly. Thus, according to Mumford, people's evaluations of creative products or individuals are not as subjective as the attribution theory explained.

Conclusion

Creativity has often been studied in terms of dispositions. Attribution theory attempts to disclose the other aspect of creativity, which is basically about social reception of original ideas. It proposes that social and situational processes can determine the creativity of the ideas because creativity is not independent of the context in which it emerged. Attribution theory deals mostly (even only) with the subjective interpretations as the causes of people's judgments about creativity. However, subjective interpretations are commonly utilized in the evaluation of creative products. Yet, this does not mean that creativity can only be explained by situational factors; or that dispositional factors do not influence creativity. Creativity is a complex process and it cannot be well understood by just one explanation. Attribution theory simply highlights another aspect of creativity's complexity.

Introduction

This essay explores the intersection of avocational pursuit with creative activity. At issue are those free-choice, non-remunerative pastimes that, as the Latin etymology of the word avocation would have it, call people away from proper work. These may range from the casual engagement of hobbies to the more extended commitments referred to as “serious leisure.” Also at issue are the skills and behaviors, purposes and outcomes that characterize human creativity. Creative activity is not to be confounded with artistic endeavor, *per se*. Rather it speaks to the combinatory processes that produce new and effective responses to cultural challenge of all kinds. How might avocational engagement inform creative contribution? If so, which avocations? By what means and to what effect? These and related questions guide modern understanding of leisure, interest and identity development, and avocational creativity.

The Leisure Question and Leisure Guidance

Modern interest in avocation and its influence on thought and behavior has historical roots in perennial conflict between work and play. Consider that the commercialization of leisure in eighteenth-century Europe raised concerns as to how different social groups chose to fill their free time. Whether the lower class worker brawled on a Sunday or attended an improving course of lectures was thought to have ramifications for Monday morning work. With hindsight, the issues of social and psychological control that ran through this and other debates may be appreciated. So, too, it is possible to recognize similar concerns at work in contemporary disputes about the amount of time adolescents or young adults spend on computer gaming, social media, or other “virtual worlds”—even as knowledge accumulates about avocations and their implications for creativity.

Avocations began to draw modern social and scholarly interest in the late 1920s, just as the stock market crash and ensuing economic depression cost enormous numbers of people their jobs. As Gelber (1991) pointed out, advances in technology had already affected the quality and quantity of work. Changes in social welfare had also made retirement possible for more people and at earlier ages. The combined result was a noticeable uptick in leisure time, both for the able-bodied and the elderly. Didactic advice for the unemployed stressed hobbies as a means of not “merely making a living, [but] actually making a life worth living” (Proctor, 1929, 356–357). Indeed, the hobby literature of the 1920s and 30s distinguished between productive and unproductive leisure, primarily, Gelber noted, “to expand the work ethic in a period when work itself was at risk” (1991, 741–742). So, too, the academic literature. How were the unemployed to acquire or demonstrate work skills and interests if no work was available? Posing that question and more, Super (1940) envisioned a reliable “guidance for leisure,” one based in the scientific study of avocation and its relationship to vocation.

Super proposed that avocations might demonstrate workforce aptitude. The question was, how might that be determined and how measured? Adapting to his purposes the Strong Vocational Interest Blank, a questionnaire that inventoried the individual’s preferences for work, amusements, and daily activities, Super compared avocational with vocational patterns among four groups of hobbyists: stamp collectors, model train/boat/airplane enthusiasts or engineers, amateur musicians, and amateur photographers. Individuals for study were solicited from hobby societies and clubs and only included teenage boys and men.

By and large, Super found that three of these groups—modelers, musicians, photographers—engaged in “vocational avocations,” that is, patterns of interests among hobbyists and professionals were similar. Model enthusiasts shared interest patterns with professional engineers. Additionally, they also shared interests with other technically oriented professionals such as chemists.

Amateur musicians were like professional musicians as well as journalists, chemists, and artists. Amateur photographers resembled commercial photographers, but also those at work in artistic, literary, and even scientific occupations. Stamp collecting alone seemed less predictive of any particular set of vocations, in part because it was unlike any one profession *per se*. It alone of the four was what Super called a “non-vocational avocation,” or true hobby. As such, it was deemed non-predictive for career guidance purposes.

Super observed an additional pattern among the hobbyists he studied. Stated as a principle, a person’s major avocation will resemble his occupation if the occupation suits his interests and abilities—in other words, the avocation “supplements” the vocation. The avocation will be different than vocation, however, if the work limits the individual’s desire to use certain of his skills or his urge to express himself in certain ways—in which case, the avocation “compensates” for the vocation. There were certain corollaries that followed: Men whose major avocations resemble their vocations will tend to be satisfied with their jobs and “better adjusted.” Those whose major avocations do not resemble their vocations and/or have a greater variety of major avocations, will tend to be dissatisfied with work and less well adjusted. Avocations, especially major avocations, were key to an individual’s “dominant interests” and the closer one could match avocation to eventual vocation the better, [Super \(1941\)](#) advised. Theoretically, he placed the individual’s psychology at the center of avocational and thus vocational choice—and allowed, too, for variation in their supplementary and compensatory relationship over time.

Serious Leisure and Avocation

Much subsequent work in leisure studies retained Super’s basic analysis of avocation and vocation: a typology of the “congruent,” the “compensatory,” and the “compartmented” or neutral relationship between work and leisure remains current today. Little effort was made, however, to explain why “particular work/leisure relationships arise – they just *are*” ([Veal, 2004](#), 110–111). Enter [Stebbins \(1979\)](#) and his lifelong study of this and other gray areas in the work-leisure relationship. From personal experience as a musician, he realized that in certain circumstances the professional and the amateur shared many qualities—especially with regard to the devotion both brought to their activities. In congruent situations, work shared some of the self-chosen enjoyments of leisure and leisure some of the serious commitments of work. Although the accepted dichotomy of work and leisure characterized the two as necessarily distinct and separate, [Stebbins \(1979, 1992, 2001, 2004\)](#) pioneered the investigation of avocation as if a vocation—i.e. as serious leisure.

Leisure is a concept that covers a wide range of activities, ranging from casual pastimes to dedicated hobbies. What Stebbins proposed to study as serious leisure was “the systematic pursuit of an amateur, hobbyist or volunteer activity that participants find so substantial and interesting that, in the typical case, they launch themselves on a career centered on acquiring and expressing its special skills, knowledge and experience” (2004, 49). Of the three types he investigated, the most relevant for understanding avocation is amateur activity. For Stebbins, the amateur was a part-time participant impelled by “necessity, obligation, seriousness, and commitment” (1979, 46). The hobbyist was someone somewhat different. Both amateur and hobbyist were practitioners with an enduring purpose, and yet their relationship to work was far different. The hobbyist, even if serious, engages in activity for which there is no known professional sphere—stamp collecting being a prime example. The amateur engages in activity for which there is a professional sphere—that of musician, for example—and yet, does so on the margins of the professional world.

Stebbins focused his research on associations of amateur actors, musicians, singers, archaeologists, astronomers, baseball players, football players, and magicians. Following his lead, other scholars widened the scope of amateur groups, particularly in art and sport. The solitary amateur proved of less concern, though Stebbins recognized the “systematic and fervent pursuit during free time of knowledge for its own sake” as serious leisure, very much like any other occupation subordinate to work (2001, 29). Possibly because these “liberal arts” pastimes do not create their own social worlds, he categorized them as hobbies. Because they do take place on the outskirts of thriving, academic professions, however, it would seem they more nearly fit the definition of avocation. No doubt in response to this and other ambiguities, Stebbins warned against drawing false distinctions among hobbyist, amateur, and professional:

...we must avoid the unidimensional thinking that pits the amateur against the professional in terms of, for example, little versus great skill, intrinsic versus extrinsic reward, avocational versus vocational orientation, or leisure versus work. While under certain conditions such dichotomies accurately describe their relationship, under many other conditions ... they badly distort that relationship. (1979, 44)

Indeed, Stebbins argued, amateurs make positive contributions to their associated professions and to society at large. Serious hobbyists and amateurs provide an educated audience for the professionals; they benefit their community by raising the level of participatory culture. The only consistent difference between amateur and professional, [Stebbins \(1979\)](#) and [Super \(1940\)](#) before him found, is one of remuneration: professionals commonly gain at least 50% of their livelihood from vocation, while amateurs typically make little or no money from their avocation. In many other ways, the two were nearly indistinguishable, particularly when engaged in “devotee occupations.” Usually found in the liberal professions and certain artisanal trades, such occupations allow the individual critical control over time and effort; they depend upon the individual’s substantial skill, knowledge, and/or experience; and they offer “significant opportunity for creative or innovative work, as a valued expression of individual personality”

(Stebbins, 2004, 9). Serious hobbies and avocations offer similar opportunity to develop creative behaviors, nurture motivation, and engage in productive creative endeavor.

Avocation and Creative Trait

Leisure in general promotes subjective well-being and life satisfaction. Serious leisure does as much and often something more. As Stebbins (1992) argued, serious leisure, like devotee work, may promote attitudes or traits that enhance creative readiness, including confidence, preparedness, perseverance, commitment, and strong identification as poet, musician, astronomer, and so forth. Psychologists point to many of the same traits and behaviors as characteristic of creative personalities. Confidence or self-efficacy, the ability to succeed in a set situation or accomplish a set task, is one. So is perseverance, the willingness to face and surmount obstacles in the way of skill acquisition, learning, and expressing. Runco suggested that persistence might actually be “a prerequisite for creative accomplishment” (2007, 295), if for no other reason than the sheer amount of time it takes to master necessary skills—at least ten years by some reckonings—or to usher an insight to fruition. Self-identification as a creative actor has also been strongly tied to actual creative outcome. Confidence in a skill set, willingness to commit for the long haul, self-identification as an artist, a scientist, a creator—these then appear to be core dispositions that shape and are shaped by avocational activity particularly and by creative activity generally.

Whether any individual, any amateur engaged in serious hobby or avocation, comes by these traits innately or nurtures them through practice is, of course, debatable. Psychologists have sketched out additional characteristics of creative personality, including openness, flexibility, tolerance of ambiguity, playfulness, imaginativeness, wide interests, and curiosity, all of which may depend on an eliciting environment as much as genetic endowment. In any event, Feist (1998) and others have observed that these traits, as well as confidence, perseverance, or practitioner identity, may make creative behavior more likely—they do not guarantee it or creative contribution. More is required, including motivation. Runco (2007) presented the case that the primary incentive for creativity is the individual’s need to actualize, to fulfill his or her potentialities. With regard to the motivations of serious hobby and avocation, scholars from Super to Stebbins would agree. Characterizing the development of new skills, abilities, and knowledge and the projection of a serious leisure identity as rewards, Stebbins put his finger on the positive emotional valence of serious avocational commitment.

Avocational Interest, Experience, and Creative Identity

Of the many personal rewards to be had from serious hobby or avocation, perhaps the most important when it comes to creative capacity is, in fact, the “durable benefit” of self-actualization (Stebbins, 1992, 126). First developed as a concept by Maslow in the 1950s, psychologists have since studied how interest, experience, and identity may contribute to the nurture of individual accomplishment. Needless to say, such study has its bearing on avocations, as well as the opportunities they provide for creative behavior and, in some cases, creative contribution.

Recall that serious hobby and avocation reflect the individual’s dominant interests. Silvia (2001) argued that these interests depend on the triggering of emotional interest. Emotional interest in this case is defined as the feeling of being engaged, caught up, fascinated, in a word, curious about some situational novelty, complexity, uncertainty, and/or conflict. Silvia’s model of interest development assumes that curiosity alone is not enough to create enduring interests, however. Magnification of some kind is required, for example, repeated encounters with activities that sustain the curiosity. Play and its persistent scenarios provide magnifying encounters for children; the play of hobby or avocation does much the same for more mature individuals. Hamilton-Smith observed that the optimal arousal of interest will tend to have a hedonic effect, “thus ensuring the continuity” of the rewarding behavior, whether knowledge-seeking or play-enhancing (1992, 249). Without repeated, enjoyable immersion in physical and mental activities, neither interests nor avocation would persist.

In fact, interests and avocations may be termed autotelic activities, intrinsically rewarding in and of themselves. Phenomenological study of autotelic activity locates the reward in a state of consciousness that Csikszentmihalyi (1975) has called the flow experience. The flow concept has been especially welcomed by scholars of leisure; Stebbins (2004) observed it may be the most studied reward in that discipline. Among other things, flow—and its outcomes—appear to be especially relevant to explaining the extraordinary commitment of the serious amateur. What does make an activity enjoyable, pursued for its own sake, in the absence of economic or other forms of support? The answer lies in a number of psychological effects that result under certain bounded conditions.

Consider those activities, whether physical (running) or symbolic (reading) or both (painting), characterized by a variety of challenges that require or call upon responsive skills (moving the body, recognizing letters and words, training the hand that holds the brush to execute the mental vision) in order to achieve some clear goal (a race run, a story read, etc.). When a more or less constant feedback lets the individual know that skill level is more or less in balance with challenge, the stage is set for psychological flow. During execution of the activity, the individual’s sense of time drops away and there is a loss of self-consciousness as attention concentrates and he or she becomes deeply involved in the action. To the extent that flow encourages repetition of behavior and activity, Csikszentmihalyi and Kleiber (1991) have argued, the immersive experience stimulates the acquisition of new physical and mental skills, which in turn contribute to an expanding sense of the self.

Sociologists have long been concerned with the formation of identity, particularly with regard to social role. In general, it is argued, individuals strive to affirm their inner nature through choice of outer activity. This is perhaps more the case for free choice,

intrinsically motivated leisure pursuits than for occupational undertakings constrained by extrinsic motivations and economic considerations. Serious and committed avocations are particularly symbolic of persona. The skills and practices of an amateur pianist or mycologist serve to represent the true self—not just to others, but to the self itself. In addition to a creative role identity, the amateur may also develop a creative personal identity, signifying “the overall importance a person places on creativity in general as part of his or her self-definition” (Jaussi et al., 2007, 248).

Along these lines, Stalp (2006) investigated amateur investment in what has been called a “subjective career.” The quilters she studied often defined success, not in terms of monetary recompense or even public artistic recognition, but in terms of values and goals independent of mainstream measures of professional achievement. What mattered was the acquisition of skill, self-expression, the gifting of quilts, and the consequent reinforcement of family ties and community traditions. Absent a recognized hobby community, solitary amateurs might also develop a sense of subjective career. M. Root-Bernstein (2014) observed that J.R.R. Tolkien nurtured interest in invented language, painting, and storytelling for many years before publication of his breakout fantasies of Middle-earth. His identity as creator was private before it was public. This expedient allowed him to reduce conflict with his role as professor of philology, and avoid condemnation from academic peers for wasting his time. Committed on his own terms to avocational world-building, he painstakingly acquired the skills, experience, and confidence that eventually led, in his case, to socially recognized creative outcome.

Avocational Marginality and the Transfer of Creative Effect

So far, this discussion of overlapping avocational and creative traits, experiences, and identities has focused on what Feist (1998) and others call motivational or affective factors. Put another way, up to now it has considered the potential for personal creativity to flourish in avocational activity. Most amateurs practice their crafts and callings in what Kuhn called a “normal” manner, i.e. in conventional terms. Normal avocational pursuit enables the individual to fulfill private aspirations for making, doing, and expressing *without* engaging in the kind of creative work liable to affect public or professional circles of understanding and endeavor. Nevertheless, some amateurs do aspire to socially-recognized achievement and some do make original contributions to knowledge and practice—Tolkien being one case in point. Most psychologists agree, however, that personal creativity alone is insufficient to explain this. Other factors affecting individual thought and activity appear to be necessary.

Feist (1998) and others have argued that norm-doubting, unconventionality, and/or asocial orientation play a critical role in publicly recognized creativity, especially that of major impact. So compelling is the case for the contrarian nature of eminent creators that marginality has often been considered a marker for extra-normal creative practice. Along these lines, Runco noted that both Skinner and Piaget explicitly recommended “intentional marginality” (2007, 285), such as reading outside one’s area of expertise or working at the far edges of one’s discipline. Sternberg (2003) argued that the individual may choose to be creative by purposefully adopting these or other likely intellectual strategies. As Stebbins (1979; 2001) pointed out, a limited marginality is also consequent to choosing avocational activity. Without violating the norms of society as a whole, amateurs find themselves on the periphery with respect, first, to their ambiguous posture between dabbler and professional; second, to their ambivalent position between casual leisure and work; third, to their “outsider position” in professional worlds, even as their skill and activity is judged by the standards of vocational practice. That said, Stebbins did not directly equate the social marginality of serious hobby and avocation with actual creative practice:

It would be inaccurate to assert that amateurs, because they occupy a marginal role, are therefore creative. But turned around, it is possible that some creative people, including amateurs (most likely those in art and science) are also marginal. (1979, 217)

In other words, for some individuals the limited marginality of a serious hobby may be turned to creative advantage, if only because the avocation provides a safe space for exploring interest absent professional risk. The question remains how. Feist (1998) suggested the necessity of additional cognitive traits or behaviors—openness (to fantasy, feelings, aesthetics and related values), flexibility (in the combination of ideas and practices), and imaginativeness (in the use of sensory based cognition) among them. Yet how any one of these dispositions may operate in the avocational setting to effect vocational outcome needs clarification. This is particularly so, when considering that the transfer of creative effect from one “social world” to another, from avocation to vocation, may actually be twofold. One might reasonably expect a dedicated amateur engaged in what Super called the vocational avocation to make creative contribution to the associated profession. It is less obvious how the amateur engaged in a non-vocational avocation might make creative contribution to an unassociated, apparently dissimilar profession. But that is exactly what occurs as cognitive strategies bridge the avocation-vocation divide.

Avocations, Tools for Thinking, and Creative Outcomes

Arts, Crafts, and Scientific Success

When and how do avocations set the stage for creative vocational contribution? First steps toward some answers emerged from the history of science and its long-standing fascination with how scientists discover and invent. By the mid-nineteenth century,

anecdotal observation had determined that eminent scientists not only had broad interests, but that these were more likely than not to manifest in arts and crafts avocations. Galton (1874) reported that unusual numbers of British Royal Society members were visually, artistically, musically, and mechanically skilled. A few years later, Van't Hoff (1878) disclosed the results of his study of several hundred biographies of famous scientists. Twenty-five percent of his sample, he found, engaged in some form of art, music, poetry, or literary composition. By the turn of the century, Claparède and Flournoy (1902/1904) announced that 52% of the professional mathematicians they studied pursued a musical avocation. In the first modern psychological study of scientific imagination, Roe (1953) found that members of the US National Academy of Sciences displayed extraordinary visualization skills. Subsequently, both C.W. Taylor (1963) and D.W. Taylor (1963) differentiated the most successful scientists from more average peers on the basis of extra-vocational literary ability and craft experience with hand tools.

Digesting this literature and more in his investigation of how scientists think and invent, R. Root-Bernstein (1989) listed over 400 scientists, inventors, and engineers known to have engaged in visual, plastic, musical, dramatic, and literary arts. Based on the evidence of memoir and self-report, he hypothesized that scientific creativity required mastery of certain “tools of thought” readily exercised in the arts, among them analogizing, pattern forming, pattern recognition, visual thinking, modeling, empathizing, and kinesthetic thinking. He further hypothesized that these mental tools helped integrate a scientist’s avocation and vocation as “correlative talents” into what Gruber (1989) called viable “networks of enterprise.” For Gruber, a network comprises work-related interests, projects, and activities that support one another, primarily by mediating intellectual frustration and distributing emotional and professional risk. Root-Bernstein was suggesting that amateur interests expressed in avocational activity—and non-vocational avocational activity at that—might also support vocational creativity, and primarily by exercising or enhancing imaginative cognition.

Subsequent statistical study offered support for Root-Bernstein’s conjectures. In a longitudinal study spanning over three decades, Eiduson (1962) had been tracking thirty-eight male scientists whose careers ranged from the mediocre to the heights of excellence, including receipt of the Nobel Prize. She noted that the highest achievers differed from the rest of the group, extending “themselves emotionally, not to mention physically, into the larger intellectual sphere of humanities without actually withdrawing time, energies and efforts from their work” (Eiduson, 1962, 258). Mining her data after Eiduson’s death, R. Root-Bernstein et al. (1995) found that the most successful scientists were all avocational artists, musicians, sculptors, and poets, whereas the least successful scientists were rarely so.

More to the point, avocations and vocational success both correlated independently with each other and with reported use of imaginative “tools for thinking” such as observing, abstracting, body thinking, modeling, or playing. The more artistic hobbies a scientist engaged in, the greater his probability of achieving eminence (as measured by paper citations). Visual arts and music were particularly predictive. In turn, arts avocations were significantly associated with thinking tools. Those who engaged in visual arts or music, for instance, tended to be highly visual thinkers, using 2- or 3- dimensional forms of imaging. Imaginative skills also directly correlated with success as a scientist. Those who were strong at visual imaging or employed kinesthetic feelings proved particularly creative in their work. In short, the more deeply engaged in arts hobbies, and the wider the range of thinking tools, the more likely the scientists were to be among the highest achievers in the Eiduson group.

Larger scale statistical study yielded similar results—and validated the arts avocation as a measure capable of discriminating between varying levels of achievement. R. Root-Bernstein et al. (2008) compared the avocational interests of all Nobel laureates in the sciences (1901 to 2000) with other elite groups of scientists, with average scientists (as represented by Sigma Xi, a scientific research organization open to all), and with the general US public. Among their findings, the avocational interests of average scientists did not significantly differ from those of the larger population. Things were significantly otherwise for elite scientists. Members of the US National Academy of Sciences and the UK Royal Society were almost twice as likely to have crafts avocations as the typical Sigma Xi member. Nobel laureates were almost three times as likely to have arts and crafts avocations as Sigma Xi members, and about 50% more likely to have such avocations than Royal Society or National Academy of Sciences members. Arts avocations effectively tracked the hierarchy of scientific contribution and success.

In subsequent study of science, technology, engineering, mathematics, and medicine (STEMM) professionals, R. Root-Bernstein et al. (2013) produced similar results: arts and crafts avocations correlated significantly with measures of scientific success and entrepreneurial innovation, as measured by patent output and the founding of high-tech companies. The effect was enhanced when the avocation was sustained, i.e. introduced in childhood or youth and maintained in adulthood. In further study of this same group of STEMM professionals, R. Root-Bernstein et al. (2019) found positive correlations also exist between particular arts and crafts avocations and particular thinking tools: modeling and playing, for instance, are correlated with persistent adult crafts avocations such as metal- and wood-working and mechanics, which are, in turn significantly correlated with patent production. R. Root-Bernstein et al. (2017/2019) observed that self-report confirms the statistics: by consciously drawing disparate disciplines such as arts and sciences into proximity, imaginative thinking tools form an important “bridge” between avocational and vocational activities. Other bridges, not yet assessed statistically, include the transfer of methods and materials, aesthetic principles, and facility with creative process itself.

Beyond the Science-Art (A)Vocation Network

To date, current evidence demonstrates strong correlation between scientific creativity and persistent avocation in arts and crafts. The question remains, is there an association between avocation, tools for thinking, and creative activity in general? R. Root-Bernstein and Root-Bernstein (1999) pored through hundreds of biographical and autobiographical records to determine whether the thinking tools germane to scientific work were also at play for creators in other fields. They were. No matter the discipline or its expressive products, creative individuals tap into sensory-based cognition before translating imagistic thoughts into words,

numbers, or other symbols. Keenly observing with all the senses, readily manipulating resultant mental imagery, focusing on essential aspects of a thing or process, patterning, empathizing, keying into bodily sensations, playing, modelling, and more all formed a core set of creative skills of universal value. Beyond the science-art nexus, thinking tools did indeed provide cognitive connections bridging different professions and pursuits.

Further investigations, both qualitative and quantitative, found that networks of vocational and avocational interest also cross disciplinary silos. In a study of imaginary world invention, M. Root-Bernstein (2014) found individuals combining apparently unlike avocations and vocations on the basis of complex play—Tolkien among them. Multi-disciplinary networks linking disparate arts, sciences, social sciences, and humanities were similarly found among Nobel Prize winners in literature. R. Root-Bernstein and Root-Bernstein (2004) reported that nearly a third of literature laureates (1901 through 2002) had adult avocations in some art other than creative writing, most often a visual art. In further ongoing study of Nobel laureates through 2008, Root-Bernstein and Root-Bernstein revised this figure to 44%. About one-fifth (since revised to 24%) of literature laureates also displayed avocational interests in science. Indeed, literature laureates were just a bit more likely to have serious interest in the sciences as Nobel chemists were to have serious interest in non-fiction prose and creative writing (19%).

Ongoing research on interest patterns among all Nobel laureates by Root-Bernstein and Root-Bernstein has further confirmed robust cross-disciplinary networks of vocation and avocation among Peace Prize winners and laureates in the economic sciences—though these patterns look quite different from those of science or literature laureates. Eighty-seven percent of economics laureates showed interest in the sciences (particularly math and physics, and to a lesser extent, psychology), yet they were far less engaged in arts, crafts, and literary writing than Nobel scientists. Peace Prize winners distributed their avocational interests rather evenly within the arts (22%) and sciences (19%), but at lower rates than science or literature laureates respectively. These distinct patterns of interest aside, the average Nobel laureate (those in science and literature as well as economics and peace) demonstrated interest and/or avocation in 2.3 out of seven activity areas or fields of knowledge and practice: arts, crafts, writing, humanities and social sciences, sciences, nature immersion, and sports. Sizeable proportions of Nobels engaged in three or more of these activity areas; very few, though there were some, engaged in six or seven. Networks of interest among Nobels run broad as well as deep (see Polymathy).

(A)Vocations and Creative Impact

Evidence suggesting that avocations do indeed have creative impact on vocations must now be considered. In studies of thousands of Israeli youth, Milgram and Hong (1993) and Milgram et al. (1997) found only one reliable predictor of career success—participation by the individual in an intellectually demanding avocation over a long period of time. Indeed, Milgram (1990) proposed that nascent creative talent be identified by focusing on the leisure activities of intellectually gifted or specially talented children. Similarly, Niemi (2015) tracked a large sample of American youth and found that, of all factors investigated (arts participation, SAT scores, diverse psychological traits), only interest in visual arts proved a statistically significant predictor of entrepreneurial behavior. In a study of self-assessed workplace habits and creative practice, Jaussi et al. (2007) and Jaussi and Randel (2014) found that senior managers benefitted from non-work experiences and knowledge, particularly those associated with extra-vocational hobbies and avocation. Not only did workers with avocations tend to report creative identity, those who brought their non-work skills to bear on work projects were deemed more creatively vocationally.

Anecdotal evidence also suggests avocational impact on vocation. Nobel Prize winner Max Planck forged his quantum theory of electrons by treating orbits in the atom as if they were vibrating strings—an exercise dependent on knowledge he acquired as an amateur pianist. Albert Einstein, another Nobel laureate, drew explicit connections between his own musical avocation and the intuitive processes of his scientific creativity. Literature laureate Thomas Mann played violin and piano and otherwise immersed himself in music—his passion for these pastimes affected the style and structure of his novels, particularly in his use of leitmotif. Economics laureate Herbert Simon, who also played piano, was legendary not only for the number of disciplines he pursued vocationally, but the for number of activities he pursued avocationally. In his case, serious hobby seems to have had impact on vocational activity by design: “I can rationalize any activity I engage in as simply another form of research on cognition ... I can always view my hobbies as part of my research” (Simon, 1996, 243).

Vocation can likewise have positive creative impact on avocation. Tolkien funneled his philological interest in languages missing from the historical record into the avocational reconstruction of a mythic “faery” tongue antecedent to Anglo Saxon. The same linguistic interests that drove his vocation also drove his avocation, though eventually Middle-earth became an imaginary world and literary pursuit of its own (M. Root-Bernstein, 2014). Maurice Allais (1989), Nobel laureate in economics, brought the periodicities of physics (which he pursued as a serious amateur, at professional levels) to bear both on his vocation in economics and his avocation in history, an ambitious attempt to draw out regularities in the rise and fall of civilizations. Contemporary visual artist Todd Siler enabled his avocational development of a fractal reactor, well-received in physics circles, with thinking and drawing processes borrowed from his art practice (M. Root-Bernstein, 2014).

As these last exemplars must make clear, the relationship between avocation and vocation is a fluid one. Creative transfer can run in either or both directions. Indeed, for many individuals, the avocation may exert the larger creative pull, such that it eventually supplants the individual’s original vocation and becomes either the sole or a dual vocation. This was true for Tolkien, as it has been for numerous others studied by Root-Bernstein and Root-Bernstein. In some cases, indeed, the avocation is less a “subordinate” passion than it is a choice made between competing vocational options. Planck might have been a concert pianist; Siler loved physics from an early age; vocational opportunity turned Allais from history towards economics. In cases such as these, the avocation does not simply fill in leisure time, but functions to maintain an individual’s multiple interests within an integrated network of

creative enterprise. Because of that integration, the avocation may have its greatest creative impact on the networked vocation. Vice versa, the “normal” practice of a vocation may have its most original and effective impact in an innovating avocation.

Implications for Future Research

In the study of avocations and creativity, much remains to be investigated. Which avocations best support endeavors beyond science? How can cognitive and other benefits of avocation be reliably investigated? How can creative transfers to and from vocation be verified? Answers to these and related questions will require more psychological and sociological study, as well as more historical and biographical case study, tracing the knowledge-making interactions between avocation and vocation for creators of all kinds. At stake is an effective understanding of the role of polymathy, transdisciplinary cognition, and leisure-work synergy in human creativity. How does serious avocation inform current academic debates as to whether creative know-how is innate or learned, specialized or universal? How do educators teach for life-long learning in a world of fast-paced knowledge innovation and obsolescence? Perhaps more than ever, avocations stand as bulwark against the tyrannies of over-specialization in education, the cult of over-work in the marketplace, and the erosion of active amateur activity in a growing sea of passive entertainments. Avocations matter and matter greatly, not just to self-fulfillment, but to socially recognized creativity. Whether personal or public, creativity requires the networking of previously unassociated interests, ideas, and capabilities, along with the drive to take upon oneself the doing, the making, and the solving of cultural challenge. By reducing emotional risk, opening up mental space for playful exploration, and providing autotelic reward for skill development and knowledge transfer, avocations play their part in that process.

Introduction

Various cultures and civilizations throughout history have used awards to honor those individuals who best represent highly valued achievements. Perhaps the most ubiquitous and conspicuous are the honors received for heroism in military combat. Examples include the French Croix de guerre, the German Eisernes Kreuz, and the US Medal of Honor. Nevertheless, some societies have also chosen to recognize accomplishments more often associated with peace rather than war. Perhaps the most salient examples are the gold, silver, and bronze medals bestowed on the top athletes every 4 years at the Olympic games. Also in this second category are various ways of recognizing major creative accomplishments. The ancient Greeks allotted annual awards to the best plays shown in the Athenian Theater of Dionysius. Multiple winners of these dramatic competitions include the great tragedians Aeschylus, Sophocles, and Euripides.

In modern times the best known awards of this kind are probably the Nobel prizes for literature and the sciences, the latter category encompassing separate honors for physics, chemistry, physiology or medicine, peace and, most recently, economics. The Nobels are international awards, but many countries feature more regional awards. Thus, the United States has Pulitzer Prizes for newspaper journalism (e.g., international reporting, feature writing, commentary, criticism, editorial cartooning, and feature photography), literary achievements (in fiction, drama, history, biography or autobiography, poetry, and general nonfiction), and musical composition. Many other awards recognize specific domains of creativity. For example, the Miguel de Cervantes Prize is awarded to the most outstanding writer in the Spanish language (but not necessarily a Spanish writer). Of a similar nature are the Goethe (German) and Camões (Portuguese) prizes. Most well-established professions will support an appropriate set of honors. For instance, research psychologists can receive the Award for Distinguished Scientific Contributions granted by the American Psychological Association.

The most prestigious awards are bestowed upon creators in impressive gala events. Perhaps the most prominent example are the Oscars given out by Hollywood's Academy of Motion Picture Arts and Sciences in a ceremony broadcast worldwide. Moreover, the recipient might receive the honor directly from the hands of a major celebrity, including royalty. Nobel laureates receive their gold medals directly from the Swedish monarch. At the other extreme, far less eminent honors might be simply announced in a press release or official newsletter.

The first psychologist to use awards to study creativity was Francis Galton in his 1874 *English Men of Science: Their Nature and Nurture*. Galton wanted to study the development factors underlying exceptional scientific achievement so he distributed questionnaires to scientists of sufficient distinction that they had been elected Fellow of the Royal Society of London. Because fellows can only be elected by previous fellows, this group formed a highly elite sample. Among the more than 100 scientists responding to his questionnaire were the mathematician Arthur Cayley, the physicist James Clerk Maxwell, the biologists Charles Darwin and T. H. Huxley, and the evolutionary philosopher Herbert Spencer. Using their responses, Galton was able to show how family background (e.g., birth order) and educational experiences (e.g., dislike for school) can affect the emergence of scientific creativity.

From time to time other researchers have followed in Galton's footsteps, Nobel laureates and Oscar winners perhaps receiving more empirical attention than any other group of awardees. To appreciate why investigators have examined awards let us first

examine the distinct advantages of this approach. Next we shall review some of the actual applications of awards to the study of creativity. In addition, the use of awards can be compared with closely related indicators of creativity. But an encyclopedia entry such as this would not be complete without discussing potential disadvantages as well.

Advantages

Among the oldest issues in the study of creativity is the “criterion problem.” By what standard do we determine that a person or product is creative? For example, suppose the investigator wanted to study the personality correlates of creative achievement among United States psychologists. One plausible solution might be to use awards and honors as an index of creative achievement in psychology. Such recognition might include election to the National Academy of Sciences (NAS) or receipt of the Distinguished Scientific Contribution Award (DSCA) of the American Psychological Association. Such honors would seem to have a *prima facie* claim to validity. After all, expert peers are almost invariably involved in deciding who receives the honors. Moreover, the recipients must normally undergo a rigorous nomination and evaluation process in which a candidate’s career is assessed with the aid of supporting documentation, often including nomination letters and complete curriculum vitae. It is reasonable to assume that those who have such honors bestowed upon them are more creative than those who do not.

As a consequence, awards and honors provide a potential solution to the criterion problem. Furthermore, such formal acts of recognition have two other assets as criteria variables.

First, they can be used to assess the magnitude of creativity. In many domains of creative achievement, awards and honors can be arrayed in a hierarchy from the most competitive to the least competitive. In psychology, for example, membership in The National Academy of Science (NAS) is more selective than getting the Distinguished Scientific Contribution Award (DSCA). Furthermore, below the latter are the various career achievement awards offered by the many APA divisions, such as the Ernest R. Hilgard Award for a Career Contribution to General Psychology bestowed by the Society for General Psychology (Division 1). Below that award might be one of the more specialized divisional awards, such as the George A. Miller Award for an Outstanding Recent Article in General Psychology (also Division 1). Lower still would be election as Fellow of APA or the Association for Psychological Science (APS). Needless to say, election to NAS does not have to represent the acme of this scale. A true elite has earned a Nobel Prize in either economics or physiology/medicine. Accordingly, we might array the award hierarchy as follows: Nobel, NAS, DSCA, APA divisional career awards, APA divisional “best” publication awards, and APA or APS Fellow status. Hence, award criteria do not have to represent dichotomous either-or measures. Instead, it is sometimes possible to define a rank-category scale.

Second, award criteria measures can be applied to different units of analysis. Some honors are routinely assigned to individual creators, whereas others are allotted to single creative products. Indeed, that contrast was already implied in the preceding paragraph. The Hilgard Award recognizes a lifetime of distinguished contributions, whereas the Miller Award honors a single notable contribution. The distinctions can be made even finer. On the one hand, many professional organizations offer “early career” awards as well as lifetime career awards. For example, APA’s Division of Developmental Psychology annually bestows the Boyd McCandless Award to young promising researchers and the G. Stanley Hall Award to those who are entering the final phase of their careers. On the other hand, some organizations may distinguish between types of creative products to be honored. Besides the Miller, APA’s Division 1 also bestows the William James Book Award. Interestingly, these distinctions may be combined to yield a honor like Division 1’s Gardner Lindzey Dissertation Award – a kind of integrated early career and best product award.

Researchers tend to use award criteria in two different ways. The first is to introduce a specific award or honor as a sampling criterion. This is what Galton did in *English Men of Science*. Only scientists who were Fellows of the Royal Academy were sent questionnaires. The second usage is to sample individuals with and without the award and then define a dichotomous variable that equals 1 if a person received the honor and equals 0 if they did not. As an example, a number of investigators have compared US scientists elected to NAS to those who failed to earn that distinction.

Illustrations

To appreciate fully the value of using awards in creativity research, extended examples are necessary. Consequently, below are overviews of two rather extensive research literature. The first concerns scientific creativity and uses the individual creator as the unit of analysis. The second concerns artistic creativity and uses the single creative product as the analytical unit. The specific topics are Nobel laureates and award-winning movies, respectively.

Nobel Prizes

Alfred Nobel was the inventor of dynamite and a major Swedish armaments manufacturer. Having read a premature obituary that condemned him as the “merchant of death,” and having never married and fathered a family, he decided to use his vast wealth to leave a more positive legacy after his death, which took place about eight years later. In his last will and testament, written about a year before his death, Nobel left a huge amount of money to award contributions to physics, chemistry, physiology or medicine, literature, and peace. The first such awards were bestowed in 1901. A prize for economics was instituted in 1968 and first awarded a year later. Because this award was not part of Nobel’s original will, some observers contest that it does not count as a true Nobel.

Nonetheless, the selection procedures for the economics prize are every bit as rigorous as the procedures for the prizes. Both nomination and selection must meet extremely high standards. For instance, the physics, chemistry, and economics prizes are chosen by five-member committees appointed by the Royal Swedish Academy of Sciences. Nominators are also carefully restricted. It often takes a considerable time for someone eligible for the Nobel to finally receive the honor. For example, Einstein received the prize for physics in 1921. The prize citation specified his work on the photoelectric effect, a contribution he made in 1905. Some potential recipients have even died before they could be appropriately honored.

Some empirical investigators have been content to study the general characteristics of Nobel laureates, often concentrating on some subgroup, such as the scientists or the writers. Although these inquiries can often yield fascinating insights into the constitution of the typical laureate, their value is diminished whenever they lack a suitable comparison group. As a result, the most useful empirical studies will introduce some type of between-group contrasts. These contrasts largely assume two forms: (a) laureates in one domain are compared to laureates in another domain and (b) laureates are compared to non-laureates.

Laureates Versus Other Laureates

Researchers have often scrutinized whether a Nobel recipient in one category differs from a recipient in another category. Some of this work has concentrated on early developmental experiences (e.g., [Berry, 1981](#)). For instance, in comparison to laureates in literature, laureates in the physical sciences are far more likely to have fathers who were academic professionals. Additionally, laureates in literature were far more prone to have lost their father during their minority years in comparison to laureates in the physical sciences.

Other researchers have examined the differential career trajectories of laureates in the various categories. In general, physicists reach their career peak earlier than chemists, who in their turn tend to peak earlier than researchers in physiology or medicine. These differences show up in the ages at which the scientists are most likely to receive their highest honor. Physicists are around 49 years old, chemists about 52, and bio-medical researchers approximately 55 ([Stephan and Levin, 1993](#)). Apparently, Nobel's in economics are bestowed to even older recipients.

The foregoing results imply that the specific nature of creativity varies across the Nobel categories. Creativity in physics has a different composition than in, say, literature.

Laureates Versus Non-laureates

Just as interesting are studies that compare Nobel laureates with non-laureates in comparable disciplines (e.g., [Root-Bernstein et al., 2008](#); [Zuckerman, 1977](#)). These investigations have found the following differences: (a) laureates are more likely to have attended prestigious universities and to have studied under previous laureates; (b) despite a strong commitment to their chosen area of research, laureates are much more likely to have many interests and hobbies; (c) laureates implement cognitive processes that are identifiably different from comparison groups; (d) laureates are more prolific, producing many more publications per year than their less illustrious colleagues; and (e) in comparison to non-laureates, Nobel prize winners move up the academic ladder much more quickly, attaining full professorship at a younger age. These contrasts often hold up even when Nobel laureates are compared to members of the National Academy of Sciences, themselves a distinctive group of scientists. When the comparison group consists of even less distinguished scientists, the contrasts most often become even more dramatic.

It should be noted that far more research is devoted to laureates in the sciences than in literature or peace. Awards in the latter two categories are often viewed as more influenced by political concerns whereas the science awards are seen as more objective. The specific achievements in the non-science awards are also more heterogeneous and controversial. The sciences have the advantage that a much stronger consensus exists on what counts as a substantial contribution to a given domain.

Movie Awards

Nobel's original intention was that the prize recognize specific achievements within one year after their occurrence. At first the prize committee tried to carry out this wish. It was for this reason that Dmitri Mendeleev was denied the prize for chemistry: His famous periodic table of the elements was already too old at the beginning of the 20th century. Nevertheless, the committee soon realized that this restriction was impractical. Time is necessary to obtain sufficient perspective on the magnitude of an achievement. Accordingly, the award is often bestowed long after the original contribution that inspired the honor. Because of the delay, the Nobel often functions as a career achievement award. When Einstein received the Nobel in 1921, the citation said that he was so honored for "for his services to Theoretical Physics, and especially for his discovery of the law of the photoelectric effect." The prize committee knew that Einstein was already better known for his special and general theories of relativity. Sadly, by the time the prize committees began to prolong the period in which eligible accomplishments would be considered, it was already too late for Mendeleev, who died in 1907.

It is interesting, therefore, that awards in the arts often insist on a one-year time window. That is, each award ceremony recognizes the greatest contributions in a given year. Thus, in the United States, the Pulitzer Awards clearly concentrate on the most recent achievements in its various categories. The same time limitation holds for the National Book Awards, all entries having to be published between December 1 and November 30 of the following year. This temporal focus is especially conspicuous for honors in theater and film, which are invariably confined to productions that appeared in a single year interval. Of the film honors, the most famous are the Oscars awarded by the American Academy for Motion Picture Arts and Sciences in Hollywood. But these are far from the only film honors. All told, more than 1500 award ceremonies are currently active, albeit the largest number of these represent local film festivals. The number of high-prestige movie awards is much smaller, and so the bulk of the empirical studies have concentrated on the Oscars alone. That will be the emphasis here as well.

As will be apparent to anyone who has watched a televised Oscar ceremony, awards are offered in numerous categories of cinematic achievement. The biggest honor is that given for best picture, followed by best director, screenwriter (both original and adapted script), the four acting awards – male and female leads and male and female supporting. Less conspicuous, but no less important, are the honors for cinematography, editing, art direction, costume design, makeup, score, song, and ending with the more technical contributions of visual effects, sound effects editing, and sound mixing. Admittedly, not all award ceremonies offer honors in all of these categories. Indeed, some will stick to only the first half dozen or so. Furthermore, some organizations will split one or more categories into more specialized achievements. The Hollywood Foreign Press Association separate Golden Globe Awards into best picture and lead acting awards for dramas and comedies or musicals. Finally, it should be observed that most organizations bestow two levels of honors – the nomination and the outright award. Given the competitiveness of these honors, receiving an “Oscar nod” is deemed no mean achievement, even if it is not followed by an Oscar statuette.

Empirical research concerning these diverse awards leads to two major conclusions (Simonton, 2011):

First, the awards and nominations bestowed by major organizations display a very conspicuous consensus for most award categories. This agreement holds independent of whether the honors are decided by professionals, journalists, scholars, or critics. The consensus is probably surprising given that some organizations presume that their assessments are truly distinct. For instance, the New York Film Critics Circle Awards were initiated as an anecdote to the Oscars, which the East Coast critics thought were contaminated by studio politics and local tastes.

Second, although the inventory of award categories is quite large, certain honors tend to go together. In particular, if we leave aside the best picture award as representing a global honor, then all of the remaining nominations and awards have been shown to form the following four creative clusters: (a) dramatic – consisting of directing, writing, editing, and acting; (b) visual – cinematography, art direction, costume, and makeup; (c) technical – visual special effects, sound effects editing, and sound mixing; and (d) musical – score and song. Notably, these four clusters do not all correlate in the same way with a film earning the best picture award: the most prominent correlation is for the dramatic cluster, followed by the visual cluster, with only one tenth the effect. The technical and musical clusters, in contrast, are not associated with best picture honors. In other words, great cinema seems to require pretty much the same aesthetic assets as great theater, namely, drama and visuals. Special effects and music are optional. Just as significant is the fact that these four clusters exhibit different correlations with other variables associated with cinematic creativity, such as production budget and screenplay attributes (See FILM).

Disadvantages

Although award measures have proven useful in research on creative persons and products, such assessments are not without problems. One drawback is that they are clearly confined to the highest levels of creativity – what researchers often style “Big C” Creativity. Everyday “little-c” creativity does not receive conspicuous recognition. At best, such creativity might earn some localized praise, such as someone getting “employee of the month” for a particularly imaginative and useful recommendation placed in the company “suggestion box.” Moreover, even in the population of exceptional creators, certain honors have rather low base rates. At present, a little over 100 writers have received the Nobel Prize for Literature since its inception. When one considers that these writers represent every major literary language and hail from every continent except Antarctica, it is clear that the vast majority of highly creative writers will never receive this award. Although many of these will be recognized by more regional awards – such as the Cervantes, Goethe, and Camões prizes – it remains the case that award winners form an elite at the uppermost tail of the creativity distribution.

Even worse, the history of any award will be embarrassed by certain numbers of false positives and false negatives. The former represent cases where someone received the honor even when he or she was undeserving. This was a principal reason why the Nobel Prize committees now ignore Nobel’s stipulation that the awards go to recent contributions. Even then, the awards sometimes go to the wrong recipients. When it was initially announced that the 1923 Prize in Medicine would go to Frederick Banting and John Macleod for the discovery of insulin, Banting protested that it was Charles Best rather than Macleod with whom he should share the honor. Banting almost refused the award, and when he finally consented, he shared half of his prize money with Best. According to Banting, Macleod’s sole contribution was to provide some laboratory space for the experiments that Banting and Best conducted.

False positives also happen in the case of awards for creative products. Film critics and historians are fond of pointing out the best picture Oscars that went to the wrong film in a given year. In 1953 Cecil B. DeMille received the best picture award for *The Greatest Show on Earth* when the other four nominees were *High Noon*, *Ivanhoe*, *Moulin Rouge*, and *The Quiet Man*. All but *Ivanhoe* are now considered much better films.

False negatives occur when a deserving person or product fails to receive the appropriate recognition. The history of the Nobels contains many examples of great creators who never received the honor. The literary prize, especially, has snubbed many notables. The false negatives include W. H. Auden, Jorge Luis Borges, Karel Čapek, Henrik Ibsen, James Joyce, Franz Kafka, André Malraux, Vladimir Nabokov, Marcel Proust, Leo Tolstoy, Mark Twain, and Émile Zola. In the early years great writers were often overlooked because of an excessively restrictive application of Nobel’s will (which might be taken to imply that the work should be idealistic), but later literary creators were often passed over for political reasons. Also, political factors have probably introduced some false positives among the literature laureates.

With respect to the science Nobels, many false negatives ensue from the requirement that the award not go to more than three persons in a given year. Notwithstanding this provision, some awarded achievements should have been credited to four or more

scientists. A case in point is the 1965 Nobel Prize for Physics that was bestowed on Richard P. Feynman, Julian S. Schwinger, and Sin-Itiro Tomonaga for their work on quantum electrodynamics. This left out Freeman C. Dyson, who had made the important contribution of showing that their independent formulations were actually equivalent.

False negatives are particularly likely when an achievement has a narrow time window for eligibility. Because Oscars are only given to cinematic achievements in a single year, the Academy cannot carry over an achievement to the next year if there are too many deserving nominees in a given year. Peter O'Toole was nominated 8 times, most recently in 2007, but only received an Honorary Award not associated with a specific cinematic achievement.

Ironically, the existence of false negatives can sometimes produce false positives. If someone in the film industry repeatedly received an Oscar nod without any ultimate success – always a bridesmaid never the bride phenomenon – then a “sympathy vote” may emerge that will award a person for an accomplishment that does not represent his or her best work. Martin Scorsese was unsuccessfully nominated for best director 5 times before receiving it on his sixth nomination, in the latter case for a lesser directing achievement and against some rather stiff competition.

The last illustration shows that awards can often be subjected to various contaminating influences that can partly undermine their validity. To offer another example from the realm of film, a picture nominated for a best picture Oscar will improve the chances of awards for those involved in making the film, particularly the high-profile directors and actors. An even more striking example is seen in those international piano competitions where the order of each pianist's performance is determined by chance. Those who perform first are at a disadvantage relative to those who perform later. In this case, success is literally a matter of the luck of the draw.

Apart from the above problems, award indicators often have limited applicability. Not every domain offers suitable awards, or at least comparable awards. The divisional awards offered by the American Psychological Association provide a good example. There are more than 50 divisions, most (but not all) offering one or more awards. Yet there is no consistency in the number and type of awards. Naturally, some of this inconsistency can be ascribed to the fact that some divisions emphasize pure research whereas others emphasize practice or application. Yet even among the research-oriented divisions, there is no consensus on what achievements to include in the award programs. The division for developmental psychology has an early career award, whereas the personality and social psychology division does not. The experimental psychology division has an early investigator award, but the winning publication has to appear in the *Journal of Experimental Psychology*. Some divisions have dissertation awards, and others do not. And so forth. This means that it would be next to impossible to use division awards to assess creative achievement in American psychology. Whether or not a given psychologist won an award would partly depend on his or her subdiscipline.

Comparisons

Given the measurement problems that can confront application of award measures, one should consider the use of alternative but comparable measures. At the very least, these alternatives can be used to crosscheck the award assessments. In any case, the alternatives differ depending on whether the unit of analysis is the product or the person.

Creative Products

The optimal manner to assess the differential creativity of separate products is often contingent on the domain of creative achievement. In the case of the sciences, many studies rely on the number of citations a given publication receives in the professional literature. Such citation counts have the advantage in that they are less selective. It is less demanding to publish an article or book that is cited by others in the field than to have the publication win a major award. Furthermore, because award-winning work is not necessarily highly cited, citation counts can provide an independent assessment of a product's impact.

In the arts, citations are less meaningful as indicators of quality, and so alternative measures are necessary. For example, the creativity of musical compositions can be gauged by the frequency of performance or recording. This approach has been used to evaluate the differential aesthetic success of plays as well. In the case of poetry, an indicator might consist of the number of times a particular poem is included in various anthologies or how often lines from that poem are quoted in compilations of great quotations.

There is one assessment technique applicable to both artistic and scientific products: expert evaluations. A most obvious example is the judgments of professional critics. As noted earlier, the evaluations of film critics have been shown to correlate with nominations and awards received in the dramatic cluster. Critical evaluations are available for many other art products, including theater, fiction, music, and even video games. In a slightly different form, the same approach can work for scientific products. In this application, experts are asked to evaluate journal articles or monographs. For example, some journals have their own “best article” awards in which members of the editorial board are asked to evaluate various nominees. Curiously, one investigation showed that the articles so honored did not exhibit higher citation rates than those not so honored. It is likely that judges require a longer time perspective than just focusing on the publications that appeared in the most recent annual volume.

Creative Persons

If the goal is to assess persons rather than products, then some of the preceding approaches can be carried over with only minor modifications. Certainly, expert evaluations can just as well be applied to individuals. In fact, such assessments were introduced early in the 20th century by James McKeen Cattell [See GENIUS AND GREATNESS]. Most commonly numerous experts in a particular domain are asked to identify the top contributors to the field. These survey results are then consolidated into a single ranking or rating. In the sciences, citation counts can be implemented, only in this case the citations involve a creator's total output rather than a single publication.

Two other measurement strategies are unique to individuals.

First, creativity can be assessed in terms of productivity, especially total lifetime output. Of course, the specifics of what is counted depend on the domain creative achievement: patents for inventors, journal articles for scientists, films for directors, etc. If the creative domain entails a diversity of products that cannot all be treated equally, then some kind of weighting scheme is applied. For example, in assessing the productivity of composers, more weight must be assigned to a symphony than to a song. Finally, if the creators under investigation are still alive, then some adjustment must be introduced for age. On the average, older creators will have accumulated more output than younger creators.

Second, creativity can be gauged according to eminence [See EMINENCE]. Typically, this might entail a measure of the amount of space devoted to each creator in standard reference works, such as encyclopedias and biographical dictionaries. To maximize reliability, these space measures should use as many sources as possible. In addition, it is often necessary to implement corrections for certain biases that sometimes intrude on such measures. For instance, reference works often devote more space to literary figures and to visual artists. Research has shown that the differential eminence of creators tends to be relatively stable over time, even across centuries. The most famous painters in the Italian Renaissance remain famous today.

Citation, productivity, and eminence measures invariably exhibit highly skewed distributions with a long upper tail. Award-winning creators are most likely to be found among the individuals in that tail. In fact, citation counts have even been used to predict recipients of a Nobel Prize. Unlike award measures, however, citation, productivity, and eminence measures can discriminate creators at the lower end of the distribution – the individuals who will never earn any major awards.

Integration

Major awards and prizes can provide widely accepted evidence of the highest-level creative achievement. Although the most celebrated awards have very low base rates, these can be combined with lesser honors to create an ordinal scale. Better yet, this scale of acclaim can be integrated with continuous measures, such as eminence and productivity, to generate a composite indicator that covers the full range of what has been called “Big-C Creativity.” Indeed, it is even possible to extend the measurement down to the lower reaches of “little-c” or more everyday creativity [See EVERYDAY CREATIVITY]. This possibility is partially realized in the Creative Achievement Questionnaire (CAQ; Carson et al., 2005). Respondents are first asked to identify the areas in which they have somewhat more “talent, ability, or training than the average person.” The specific domains are visual arts (painting, sculpture), music, dance, individual sports (tennis, golf), team sports, architectural design, entrepreneurial ventures, creative writing, humor, inventions, scientific inquiry, theater and film, and culinary arts. Then for each of these areas the respondents address a series of questions that define an 8-point scale, with 0 indicating the absence of any talent. Beyond this zero point are inquiries about low-level creativity, such as taking music lessons or having performed in a play. Higher up come more demanding criteria, including publication, shows, grants, critical reviews, citations, and special prizes. Although the awards are designated as local or national, it would certainly be possible to add a higher point on the scale to allow for the receipt of international awards, such as a Nobel or an Oscar. Such an extended version of CAQ would then span the complete spectrum of domain-specific creativity, from none whatsoever to the highest imaginable.

It is hoped that someday awards will be incorporated into such an inclusive measure of creative achievement. CAQ scores have been shown to correlate positively with alternative indicators of creativity, such as divergent thinking and creative personality [See DIVERGENT THINKING; PERSONALITY]. Such scores also correlate with other dispositional traits that are independently correlated with creativity, such as openness to experience and defocused attention. Therefore, high-prestige awards can be used to discern whether these same correlates help account for some fortunate creators managing to receive the highest levels of recognition. To illustrate, does a Nobel laureate differ from a Fellow of the National Academy or Royal Society in the same way that the latter differ from a scientist who received lesser honors? It is conceivable that a single psychological continuum connects the lowest levels of creativity with those that are the most universally acclaimed.

Glossary

Insight A solution that seems to arrive suddenly, in an a-ha moment, but is actually the result of a protracted process.

Intrinsic Motivation An interest in something that comes from within the individual rather than outside of the individual. In the operant view experience with reinforcers in one's past can lead to what appears to be intrinsic motivation but instead is due to "reinforcement history."

Learning In the operant view learning occurs when behaviors change. This occurs when consequences (reinforcers or punishers) are associated with particular voluntary behaviors, or operants.

Let-it-happen A kind of tactic where the individual focuses elsewhere and thus allows certain preconscious processes to contribute to the creative process.

Make-it-happen A tactic where the individual directs thinking and intentionally works through a method for finding creative ideas.

Operant A voluntary behavior, intentionally emitted to earn a reinforcer or avoid an avoid a punisher.

Shaping The method of successive approximation which can be used to teach new behaviors.

Spontaneous Integration An explanation for insight which points to the coming together of previously learned responses but discrete into one seemingly new insightful behavior.

Introduction

In one sense it may come as a surprise that the behavioral view of creativity owes much to B. F. Skinner. After all, Skinner is known to have focused on observable behaviors. A careful reading of his work shows that he did not really think that other things (not easily observed nor measured) were unimportant. Rather, he felt that they were outside of the realm of the sciences. He was interested in predicting and controlling behavior and felt that if you could not do both of these things, the explanation of behavior was unscientific.

Late in his career he worked with Robert Epstein on a series of fascinating studies focused on topics that, at first blush, might not seem to be under the umbrella of behaviorism at all. They examined self-concept, for example, and insight. The work on insight is quite relevant to theories of creativity. A number of theories look to insight and to the a-ha experience that sometimes indicates a creative breakthrough (e.g., Gruber, 1981; Wallace, 1991). Skinner and Epstein had a behavioral explanation for insight. They were able to predict and control it.

This research offers another surprise: they worked with pigeons. They not only predicted and controlled insight, but they did it in a species with a puny brain (and cortex-to-body ratio).

It is easy to summarize the work of Skinner and Epstein on insight: Pigeons first had their wings clipped so they could not fly. They were then "conditioned" to recognize pigeon food which was shaped and colored to look like a banana. Why a banana? Because this research in many ways followed that of Hans Kohler, who worked with the famous ape Sultan. And of course apes like bananas. Kohler used banana as reinforcement for Sultan.

Sultan needed no conditioning to recognize a banana as reinforcement. In one experiment Kohler placed a banana outside of Sultan's cage and just outside of Sultan's reach. As you can imagine the cage had bars, and Sultan held on to those bars and spied the banana. But he did not use trial-and-error to discover how to reach the banana. This was Kohler's breakthrough, described in *The Mentality of Apes* (1925). It made him famous for he showed that a subhuman species could think in a fashion that did not depend on trial and error. He demonstrated that apes can think insightfully. Sultan's insight was apparent in that he looked at the banana outside of the cage. If he used trial and error he might have gone over to a wooden crate that was in his cage and tried to fit it through the bars to reach the banana. He might have tried his left arm and then his right, and then his left again. He might have tried the tire that was in his cage, as a toy, and then the Samsonite luggage that would someday be used for a commercial, to show how tough luggage should be. Sultan did none of this. Instead he looked at the banana, then looked around the cage—and spotted a stick. He looked at the banana again, and then grabbed the stick and used it to extend his reach and was able to bring the banana close enough to grab and eat. He was of course reinforced for this by the banana itself. Most importantly, there was no trial and error. Just an insight.

In a second experiment Kohler hung a banana from the bars that made up the ceiling of the cage. The banana was again out of reach. Sultan had a problem: how to get to the banana? This time he stood below the banana and looked up. Once again he did not use trial and error and did not try the tire, the stick, nor the luggage. Instead he looked at the banana, looked at the crate nearby, looked at each again, and then moved the crate, jumped on top of it and was able to reach the banana. He was again reinforced by eating a banana, and again there was no trial and error.

Apes are not dissimilar to humans. They are mammals and have large brains. They have a respectable cortex-to-body size ratio. It was a big deal in 1925 that Kohler showed a subhuman species to have the capacity for insight, but it is not a big deal in 2020. Indeed, such sophisticated problem solving has been seen in other species, including elephants and otters. But birds?

Skinner and Epstein conditioned pigeons to solve the banana problem. They proposed that what looked like an insight—a sudden a-ha solution—was actually an integration of previously learned “operants.” These are simply behaviors that operate on the environment to obtain a reinforcer or avoid a punisher. With this in mind Skinner and Epstein conditioned a pigeon to eat pigeon chow that looked like a banana. That probably was not so difficult because it was, after all, pigeon chow.

Next they conditioned a pigeon to push a small crate-like object around the cage. This was a bit more time consuming, but not much. Shaping was used. This is the method of successive approximations, where one behavior, which is in the organism's existing repertoire, is reinforced, so it occurs again. And again. And again. For the pigeons this was probably something like looking at the small crate. Once they did that reliably, a new approximation was required: moving towards the crate. That was reinforced for a while, until it was reliably emitted. Then they had to touch the crate to earn chow, and eventually they had to pick up the crate (using their peaks) and then stack one crate on top of another. All of this was done discretely in the sense that only one behavior was reinforced at a time. If the pigeon was reinforced for stacking the little crate, the pigeon was not reinforced for anything else (e.g., merely looking at the crate or merely pushing the crate). This was a critical aspect of the research: only discrete behaviors were reinforced, one at a time. The chain of behaviors (looking, then approaching, then pushing, then stacking) was never reinforced.

This is important because that “spontaneous integration of previously learned responses” is what constitutes the insight. And indeed, when the pigeon was placed in the cage with the banana-shaped chow hanging from the ceiling it basically did what Sultan did. Look at the banana, look around the cage, look at the banana, look at the crate, and boom—insight. The pigeon integrated the discrete responses and approached, pushed, and stacked the little crate, hopped up and ate the banana shaped chow. One behavioral interpretation of this is that there is no need to attribute this solution to insight. It can instead be attributed to previous experience and, when needed, the spontaneous integration of previously learned (discrete) responses, each of which was learned via shaping and reinforcement.

Insight is not creativity, and pigeons are not humans. Still, this work exemplifies the behavioral idea that highly objective methods, focusing on observable behaviors (operants), can explain much, including some things that are relevant to some creative breakthroughs.

There is much more to the behavioral approach. One intriguing idea that was not in Skinner's experimental work can be found in his suggestions for scientists (e.g., “A Case Study of the Scientific Method”). It which to imply that intrinsic motivation was important in his career. He wrote, “when you run into something interesting, drop everything and study it” (p. 223). Note that Skinner did not refer to intrinsic motivation, and in fact one very clear message that comes across when his work is read is that language must be precise. In research it should be operational.

The Big Problem: Explaining Originality

One of the biggest problems in creativity research involves explaining originality. This is critical because originality seems to be a prerequisite for creativity. The standard definition of creativity, for example, requires that creative things are original and effective. Both of these terms may vary some, originality sometimes being called novelty, for example, and effectiveness sometimes called utility, relevance, aptness, or value.

Are humans even capable of originality? This question is rarely asked, but it is occasionally implied. It arises with certain definitions of creativity. In quite a few of these creativity is defined as a combination of existing mental elements, in which case the result

is not really new and original but is instead just a new combination of what existed before. Then there is the view that everything we think is in some way tied to what we have thought before. This line of thought often points to analogies, and certainly many creative things have been found using analogies. The steam engine is often described in this way, for example, as is Velcro. At the extreme the use of analogies also implies that what is viewed as creative is not entirely original but is based on what is already existing. This question of originality is implied by the behavioral view. Think back on the spontaneous integration of previously learned responses. The only original part there is the integration; everything else already existed.

A rebuttal to the question of behavioral originality may be found in work with yet another subhuman species, namely the porpoise. In this work, reported by Pryor, Haag, and O'Reilly (1969), porpoises were conditioned (and presumably reinforced with fish). The porpoises were not, however, conditioned towards any one particular solution to any one particular problem. They were instead conditioned to emit leaping and swimming behaviors that they had never done before. In this manner they were reinforced for novel behaviors, not mere recombinations. Recall here that novelty is often a synonym for originality. This research demonstrated that novel behaviors could be learned, increased, and controlled.

Research With Humans

Research not long after that of Pryor et al. used a similar method with children—and demonstrated that they could also emit novel behaviors. And in this research the children were reinforced for novelty in one domain (e.g., finger painting) and the novelty generalized to other domains (e.g., block building). This is critical because a second question sometimes leveled at the behavioral approach concerns generalization. That may be defined as the degree to which something learned in one setting (e.g., the laboratory) is later expressed in another setting (e.g., the natural environment). The research with finger painting and block building demonstrates that generalization can be brought under operant control.

Other relevant work includes a series of studies, many with Sidney Parnes as one of the authors, and used behavioral methods with human students. This research is directly relevant because the outcome measures included tests of divergent thinking, and these may be the most commonly used measure in the creativity research. Divergent thinking tests are reliable estimates of the potential for creative thinking. They are not synonymous with creativity, but no test is, precisely because tests sample behavior and therefore are not equivalent to what occurs in the natural environment.

Research with students used a method developed by a student of Skinner's. His name was Fred Keller and he made a name for himself with the Keller Method of Instruction. That method extended behavioral concepts to teaching. It allowed individualized instruction where students work at their own pace, with clear feedback (reinforcement), and, very importantly, unit mastery. The last of these means that students do not progress from one unit or one small section of the material until they have mastered it. Mastery may be 95% on a quiz, or a bit lower, but it is always a very high criterion, which is why the label "mastery."

The results of this work, using Keller's extension of Skinner's behavioral principles, were quite clear. Students in the experimental groups which received instruction via the Keller method outperformed a control groups on various indicators of creative potential, including those based on the divergent thinking tests. No improvement was seen in a personality measure of creativity, but this was easy to explain: personality traits are known to be stable and thus not sensitive to short-term training or enhancement efforts. Divergent thinking, on the other hand, can be improved with short-term training, and the Keller Method showed improvements in the ideation that is targeted by divergent thinking tests.

The Keller Method was not developed by Skinner himself, and in fact quite a bit of the work reviewed earlier in this chapter focused on insight was conducted by Robert Epstein, not Skinner. Yet Skinner had an interest in creativity. That is evidenced by much of his early work, including "The alliteration in Shakespeare's sonnets" (1939), "Has Gertrude Stein a secret?" (1934), and "The psychology of design," (1941). These three essays were examined closely by Runco in a 2019 volume that focused on individuals who influenced the field of creativity before 1950. Here it will suffice to say that Skinner held a keen interest in creativity, and for that reason studied artists (e.g., Shakespeare and Gertrude Stein) and the artistic process. His behavioral inclination is very clear in his essays about those artists. And importantly, Skinner himself dabbled in the arts. His work of fiction entitled *Walden II* is still in print.

Before leaving the topic of the arts and artists there is one more behavioral perspective that should be noted. This was Skinner's explanation for the "starving artist." Critics of behaviorism pointed to starving artists (i.e., artists who invest their time into their art even without monetary reinforcement) as a situation where behaviorism failed. After all, starving artists are not paid and not reinforced and yet they continue to emit the (artistic) behavior. Skinner's rebuttal was that the artists had a reinforcement history that led them to invest in the art. Thus there was something in their past, where they were reinforced for art, and so even though they are no longer reinforced in the present, they continue to display the behaviors and produce art. This kind of thinking is a part of behaviorism; it explains how certain behaviors generalize or are maintained. In operant theory behaviors can be conditioned with particular reinforcement schedules so that behaviors no longer actually need reinforcement, or at least not every occurrence of the behavior. Intermittent reinforcement, for example, is given once in a while, and not in a predictable way, but since once in a while it is associated with a particular behavior, organisms learn to emit the behavior over a period of time, even without regular reinforcement. Playing a slot machine and video games may be explained in this fashion, as can fishing. They are intermittently reinforced. Maybe the arts can too.

Final Comments

This entry reminds readers that Skinner's research on behaviorism and operant psychology is still used. It is easy to see how certain behavioral ideas might be applied to creativity. Admittedly the term creativity may not align well with operant thinking, which is why there was research on insight and novelty, if not creativity per se.

One very important assumption about the operant perspective is that organisms emit behaviors in order to earn or avoid consequences (reinforcers or punishers). When it is a human, there is a decision involved; certain behaviors are chosen. This is quite important because there is also a line of thinking in the creativity research which emphasizes decision making and choices. In that sense it should not be surprising at all that certain ideas from the behavioral school of psychology apply to the study and understanding of creativity. Admittedly creativity is not yet accurately predicted and controlled, which were the goals of B. F. Skinner, but progress is being made.

Glossary

Bipolar mood disorders A group of related mood disorders described in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, (DSM-V) (2013). These can be serious, but they are also often effectively treated. Bipolar disorders are characterized by the presence of an episode of unusually elevated mood, but they typically also involve episodes of depression; these episodes of high and low mood frequently alternate with periods of normal mood. Several types of bipolar mood disorders can be distinguished. Bipolar disorder (sometimes termed bipolar I disorder), formerly termed manic-depressive disorder, is defined by a history of one or more episodes of mania – a severe mood elevation that can be euphoric or irritable but causes serious adverse consequences for an individual, such as becoming psychotic, having to be hospitalized, or experiencing severe occupational or social impairments. Hypomania involves an unusually expansive or irritable mood but is milder than mania. Bipolar II disorder involves episodes of severe depressions, along with one or more episodes of hypomania. Cyclothymia is a chronic disorder in which the person experiences many episodes with hypomanic symptoms, as well other episodes with depressive symptoms that are less severe than in bipolar I or II disorders. Bipolar disorders run in families. A familial liability to bipolar disorder is manifested in a wide range of psychiatric syndromes, from mild to severe. Liability is manifested more frequently as depression than mania. A person who carries liability may not even experience symptoms (although subclinical manifestations, including mood elevations, have been postulated).

Compensatory advantage A biological model of inherited disorders for which a psychological parallel has been suggested. In biology, there are inherited liabilities that run in families and not only increase vulnerability to illness, but are also tied to positive characteristics that run in the same families. An example is sickle cell anemia, a recessive genetic disorder in which individuals who inherit a copy of a mutant gene from both parents experience serious, often fatal, medical complications. However, individuals who inherit only one copy of the mutant gene usually have relatively mild symptoms, and these carriers of the gene gain an important compensatory advantage resistance to malaria. A compensatory advantage involving enhanced everyday creativity has been suggested in connection with genetic liability for bipolar disorder. Research in Iceland and Sweden has found that variants of certain genes are associated with both increased risk for schizophrenia and increased creativity. This suggests that variants of some genes that increase liability for schizophrenia also may have a compensatory advantage: an

association with increased creativity in mentally healthy individuals. The research also suggested a possible analogous finding for genes in bipolar disorder (see Keller and Visscher, 2015).

Eminent creativity This term applies to outstanding creators or creative accomplishments where recognition has been given by society or by relevant professional organizations in forms such as prizes, awards, honors, or publication. The quality of originality or novelty is generally part of what is recognized. Eminently creative individuals and their accomplishments are thought to have exceptional qualities or importance in their cultural context.

Everyday creativity This term applies to creators or creative accomplishments that involve day-to-day activities at work or leisure and are characterized by both originality (involving new and unusual aspects) and meaningfulness to others (rather than being completely random or idiosyncratic). Many types of activities qualify, and they can be concrete products, behaviors, or ideas. The creativity has more to do with how a task is done than what it is called. For example, while the painting of a scene would typically involve significant creativity, it may not if it simply involves following 'paint-by-number' instructions. Everyday creativity can be expressed in a variety of activities, including, for example, making home repairs, designing children's activities, reorganizing an office, counselling a friend, doing gourmet cooking, or charitable work – so long as the activities involve significant originality and are meaningful or adaptive.

Inverted-U effect This phenomenon refers to a curvilinear relationship between two variables, in which both high and low levels of a predictor variable are associated with lower levels of the outcome variable, whereas an intermediate level of the predictor variable is associated with the highest, or optimal, level of the outcome variable. Some research suggests that certain psychological characteristics related to bipolar liability, when they are neither too strong nor too weak, may be associated with higher creativity, showing an inverted-U relation between bipolar liability and creativity.

Unipolar mood disorders Unipolar disorders are characterized primarily by periods of unusually low mood, usually alternating with periods of relatively normal mood. Adverse effects of depressed mood on other psychological functions are also typically present, such as disturbances in sleep, appetite, and energy. These mood disorders can range from major or severe depressions to milder ones, and these milder forms can sometimes take the form of more pervasive or long-lasting dysthymias that involve dysphoric mood. These disorders can be extremely serious, but effective treatments for them are often available.

Introduction

Throughout history, one finds the notion of a link between creativity and psychopathology, going back to pre-Grecian myth and Plato's divine madness. As will be discussed, there is scientific support from recent research for this long-standing belief in an association between increased creativity and psychological disturbance. Particularly among eminent creators in the arts, there are very high rates of major mood disorders, both bipolar and unipolar. This evidence from recent research fits with the findings of older studies. Among eminent creators in non-artistic fields, however, the patterns of relationships involving mood disorders are more complex.

In studying everyday creators, researchers have tended to start with samples of subjects chosen for clinical reasons rather than their creativity. This is a key difference from the research design used in studies of eminent creators, as will be discussed. Research evidence to date also supports the presence of a significant advantage for everyday creativity – for originality in everyday life – in individuals with a personal or family history of bipolar disorders. The most creative individuals may not themselves be the most severely disordered, in accordance with an inverted-U hypothesis of the relation between creativity and liability for bipolar disorder. The most creative person in a family with bipolar disorder may often be one who is psychiatrically normal. In the latter case, what may be important is not the presence of psychiatric symptoms in a particularly creative person, but rather some positive and subclinical psychological traits that run in the families of people with bipolar disorder.

Research findings suggest the optimistic view that a creative advantage associated with liability for bipolar disorder is not directly linked to the pain and suffering that can accompany mood disorders, but rather to a more positive psychological factor. Moreover, some research raises the question of whether there are creative advantages that, in themselves, may heal or even protect against development of full-blown mood disorders. Further work on this issue is needed. These issues are important because of the sheer numbers of people affected by mood disorders. By some estimates, as much as 4%–5% of people in the general population may end up developing a 'bipolar spectrum disorder,' ranging from rather mild to quite severe in degree. If each affected person has even one non-mood-disordered relative carrying a familial risk, as much as 10% of the population could have a heightened potential for everyday creativity and its benefits.

Finally, a note of caution is in order. We are discussing some serious and painful mood disorders, including major depressions and bipolar disorder. It is important not to romanticize these disorders just because creativity might at times be involved. The problems associated with these disorders are severe and often life-threatening. Without treatment, roughly one out of five people with a bipolar disorder will end up taking his or her life. This outcome is particularly tragic, given that treatment can often be highly effective. Furthermore, it appears that treatment may often increase creative potential and achievement. Treatment options should be carefully investigated by anyone who has, or is at risk for, a mood disorder.

Spectra of Mood Disorders

Mood swings appear to fall along a broad continuum of severity. At some level, they may even affect many people in the population at large, as found in one clinical study in which 40% of the control group showed cyclical mood swings that were milder but similar in periodicity to those of a clinical sample. Another major study found that during colder months of the year a great many people suffer at least a few minor symptoms of winter blues or seasonal affective disorder.

Traditionally, there are two broad classes of mood disorders: major depression and bipolar disorder, estimated by some studies to affect roughly 5%–10% and 1% of the population, respectively. Even here, though, there are further spectra, which range into milder variants. The underlying risk for mood disorders displays a strong genetic influence, as shown by the results of adoption and twin studies. However, there is also a large (but poorly understood) environmental component. Bipolar risk or liability involves a more marked genetic component than does risk for unipolar depression. In fact, research suggests implications for enhanced creativity in the relatives of persons with bipolar disorders, even including the psychiatrically normal as well as the unipolar depressed relatives of people with bipolar disorders. Hence, it is important to consider both personal and family psychiatric history.

In defining mood disorders, one should note that there are many more features required for diagnosis than the few given here; these features are listed in the *Diagnostic and Statistical Manual*, fifth edition, (DSM-5) (2013), of the American Psychiatric Association. In a family at risk for bipolar disorder, depressive manifestations can range from dysthymias and milder depressions to severe major unipolar depressions (all of these can occur without a history of clinically significant periods of mood elevation). As noted in the glossary, there are bipolar disorders of varying severity. These include bipolar I disorder, bipolar II disorder (which involves milder mood elevations alternating with episodes of severe depression), and cyclothymia (which involves milder mood swings that may be rapidly alternating). Especially in bipolar I and II disorders, there may be long periods of normal mood between such mood swings. A smaller number of individuals in families with a history of bipolar disorder may show ‘schizoaffective’ disorders, which are characterized by the presence of psychotic features, such as hallucinations and delusions, that occur when the person is experiencing episodes of mania or depression. In summary, a bipolar liability can be manifested in a variety of ways.

The course of mood disorders can also vary dramatically, in both quality and quantity. For example, some people may have only one episode of depression in their whole life, whereas others may experience dozens of depressive episodes. In addition, some people with mood swings may also spend a great deal of their time in a state of relative euthymia, or normal mood. Thus, most individuals with mood disorders do not have an ongoing chronic and unchanging depressed or manic state – a factor that may be important to creativity. Both temporary psychological state factors and ongoing trait factors may be significant.

Bipolar–Unipolar Disorder Distinctions

At this time, research is more plentiful on creativity in families with bipolar compared to unipolar disorders. It is worth repeating that pure unipolar depression is an even more common outcome in individuals with a bipolar family history than are bipolar mood swings, and that such depression may also predict for creativity. One preliminary study suggests, for example, that creativity may be higher in depressed patients with bipolar disorder in their family than in depressed patients without this family history. Perhaps there are subtle and subclinical factors operating – even ones that are adaptive and positive – beyond the more debilitating symptoms. This issue needs careful study. Clinicians can be so intent on sniffing out psychiatric illness and dysfunction that they fail to notice when something is going right, such as unusual creativity.

The several sections that follow concern issues of (a) eminent creativity and mood disorders; (b) everyday creativity and mood disorders; (c) mood disorders, creativity and evolution; (d) biological models in which illness and health may be intertwined; and (e) conclusions and recommendations, including some optimistic implications for fostering creativity potential as well as for better treatment and prevention of mood disorders.

Eminent Creativity and Mood Disorders: Considerations

There is evidence for an association between creativity and bipolar disorders, but the answer depends upon the way the question is asked; see, e.g., Richards (2010) for more discussion of this point.

Defining Creativity, Defining the Question

People often identify creative outcomes using a minimum of two criteria involving (a) originality and (b) meaningfulness to others (as opposed to randomness or idiosyncrasy). With eminent creativity, there is the additional criterion of social recognition of the creative activity – the achievements and their creator have been recognized and won acclaim, either from society at large or from people in particular fields or subpopulations. Many people think of creativity largely in terms of people with eminent accomplishments – for example, the novels of the best-selling authors, the discoveries of Nobel prize-winning scientists, or paintings that went for millions at an auction. Such creators, or creativity, should have some different ingredients from those associated with everyday creativity.

A critical caution: the question one asks helps determine the answer. The results of research depend on whether one is studying (a) eminent versus everyday creators; (b) people chosen for mood disorders rather than their creativity (the second can be an overall

better-functioning group); (c) patterns across families versus within individuals (in families one can find examples of both unusual creativity and mood disorders, though not necessarily in the same person); or (d) a particular field of endeavor (e.g., the arts versus the sciences).

Elevated Rates of Bipolar Disorders in Eminent Artists and Writers

Several modern studies of artistic creativity and mood disorders are notable because they provided more solid support to a range of older and less rigorous studies that pointed in the same direction. For example, in the study by Andreasen (1987) of 30 well-known creative writers who were teaching at the renowned Iowa Writers Workshop, a remarkable 80% had a history of a major mood disorder (compared to 30% of controls). In addition, over half of those affected had a form of bipolar disorder, and a little over half of that number had a history of a bipolar II disorder, showing milder mood elevations.

Supportive evidence was obtained by Kay Jamison (1989), who asked 47 highly distinguished British artists and writers if they had been treated for a psychiatric disorder. A full 38% said that they had been so treated, with mood disorders again highly prominent. These percentages are almost certainly under-estimates of the rates of mood disorders in these eminent creators, because only about one out of three mood-disordered persons currently tends to seek help at all (a particularly sad fact, given the efficacy of treatment). Furthermore, a full 89% of these eminent persons had had intense creative episodes (of a modal length of two weeks), which showed many of the symptoms of clinical hypomania. Finally, these rates may be compared to the lifetime prevalence of bipolar and unipolar disorders in the population at large, which are substantially lower, in the range of 1% and 5%–10%, respectively.

These results support findings from a range of older studies' findings from the 19th century to the early 20th century, which also indicated a creativity–psychopathology connection, particularly in the arts, where most of the work had been done. Despite varied research design flaws, these older studies tended to point in the same direction, supporting a connection between artistic creativity and psychopathology, particularly mood disorders. See review by Richards (1981).

Research on Scientific Professions

An older study that included scientists showed them to be a healthier group than artists on average, with nonpsychotic disorders only about half as common as in artists. More modern research supports this conclusion, including Ludwig's finding that across 18 occupational groups, there was a much healthier picture for non-artists than for artists – or else, the mental illness in scientists was less obvious or less likely to be reported. Social scientists showed rates of depression in the mid-20% range, and physical scientists showed rates in the low teens. Other groups showing lower rates of psychopathology included businesspersons, explorers, athletes, military figures, and social activists.

More subtle bipolar disorders and family history were not assessed. Still, where overt mood disorders are concerned, the best predictor is not being an eminent creative person but, rather, an eminent creative artist. Note, however, that there are many mood-disordered people who do not become eminent, or even highly creative. What other factors might combine to make the achievement of eminence in Western culture more likely? An experiment by DePetrillo and Winner (2005) found that doing creative artwork elevated self-reported mood in college students in whom low mood had been induced by exposure to videos showing distressing scenes. By contrast, simply copying abstract designs or solving challenging verbal puzzles did not elevate mood significantly. The mood-elevating effects of creative artmaking may make artistic endeavors especially attractive to individuals with mood disorders; this may help explain the over-representation of individuals with mood disorders among creative artists.

Kyaga et al. (2011) conducted a study in Sweden of over 300,000 people, using anonymized data from national hospital records and census data for an entire national sample of all patients with bipolar disorder, their biological relatives, and controls without a personal or family history of mental disorder. The authors compared the rates of artistic and scientific occupations – considered to be more creative – reported on census records, in the patients, their relatives, and controls. Individuals diagnosed with bipolar disorder were significantly overrepresented in creative occupations, an effect largely due to higher rates of visual (e.g., photographers and designers) and non-visual artistic occupations (e.g., authors and composers). The close relatives of the bipolar patients also reported elevated levels of creative occupations, but in contrast to the patients, the increase was greater for scientific than artistic occupations (Scientists were considered to be people who did research or taught at a university level). It is noteworthy that the researchers found, for both bipolar disorder and schizophrenia, that rates of creative occupations were greatest for the healthy first-degree relatives of patients, rather than the patients themselves.

Eminence Revisited: A Complex Equation

Robert Albert (1996) identified a finite number of early personal and family factors that may together yield a 'multiplier effect' on eminent achievement. These include parental and sibling characteristics, and family birth order. Many positive forces combine to provide personal strength, support, opportunity, and expertise. Albert also found that long-standing family interests or capacities were frequently made available to the individual, allowing a channeling of interests and a long-term immersion in a subject, with support of family and culture.

Strong motivation is important for creativity, especially for the creator with a bipolar disorder. Ruth Richards and Dennis Kinney have shown a definite preference for work-related over leisure-related creativity among bipolar subjects in a sample of everyday

creators. (By contrast, other research by Kinney et al. (2001) found that individuals with schizotypal personality traits, which are elevated in the relatives of schizophrenia patients, showed greater preference for leisure-related creativity.) A number of personality factors linked with bipolar mood disorders have been proposed that may raise the chance of eminent recognition when creative talent is already present. These factors include a driven work orientation, an ability to think in broad and ambitious terms, altruistic and socially concerned motives that may accompany mood elevation, a sense of 'standing apart' from the main-stream, and a need for external validation.

Results were similar for both artistic and non-artistic fields. Personal characteristics associated with creativity have included contrariness, capacity for solitude, physical illness or disability, drive for supremacy, production of work with a personal seal or signature, and a psychological 'unease' or drive. Mental disturbance is included in the 'unease.' Research on eminent individuals has found that psychopathology was four times as common in the most eminent as in the less eminent individuals.

Everyday Creativity and Mood Disorders: Considerations

Subjects Chosen Using Clinical Versus Creative Criteria

Let us now turn things around and start with subjects who are chosen because of their psychopathology, rather than their creativity. If all creative writers had mood disorders, one would not expect everyone with a mood disorder to be a creative writer. One still does hear, however, people making these associations of mood disorders with creativity as if the association were (a) always true and (b) reversible. It is not so. These associations are not predictive, probabilistic, and directional. Creative writers, or indeed people in any field who have achieved a measure of success, bring together a constellation of intellectual and personal qualities and strengths. This constellation might not be the case for the average person on the street, or for someone with a severe mood disorder. When we focus on eminent creators, we are not at the less-productive extremes of bipolar liability in the inverted-U relationship between symptomatology and creativity, but rather are somewhere into the more functional middle (raised) segment of the inverted-U curve.

Compensatory Advantage? A Key Study and Method

The phenomenon of compensatory advantage may be relevant to creative ability. In sickle cell anemia, inheritance of the same recessive mutant gene from both parents leads to serious and often fatal medical disease. By contrast, inheritance of only one copy of the mutant gene (i.e., carrier state) may often result in only a mild anemia, while providing a compensatory advantage of resistance to malaria. In the case of some psychiatric illnesses such as bipolar disorder, while the genetic model may be more complex, it seems plausible that certain genes that increase risk for the disorder may also carry a compensatory advantage involving increased creative potential. The numbers of people affected is important; millions of people are affected by mood disorders, so that the benefit of increased creativity would affect not just the achievements of a handful of highly eminent people, but the everyday lives of millions of individuals. This phenomenon may also involve a more complex variant of genetically based selection, favoring people who may contribute to memetic (or informational) evolution, as well as genetic evolution. Creative individuals facilitate growth in the units of information (or memes) that reflect creativity in the world, and these may subsequently affect genetic survival, as in the discovery of fire or of penicillin.

Accordingly, an inverted-U association has been hypothesized between creativity and degree of bipolar symptomatology. Richards, Kinney, and colleagues compared the creativity of individuals with bipolar disorder, patients with cyclothymia, and their psychiatrically normal relatives to each other, as well as to psychiatrically normal control subjects, and to individuals with another type of psychiatric diagnosis. The creativity variable involved a measure of the highest or peak level of real-life broad-based everyday creativity manifested in vocational and avocational activities, rated using the *Lifetime Creativity Scales*, consistent with evidence of a disposition toward originality. The mean rating for everyday peak creativity was higher among the clinical sample (comprised of bipolar and cyclothymic patients and the normal relatives) than controls, with the cyclothymic group showing higher creativity than the bipolar group. However, another group was also highly creative: the psychiatrically normal relatives of bipolar patients. See Kinney and Richards (2014) for a review of this research.

This is an important finding, indicating that the severe pain and suffering associated with full-blown mood disorders were not necessary for the hypothesized creative advantage. Nor did psychiatric normalcy explain the high level of creativity in the healthy relatives of bipolar patients, since the normal control subjects were not so distinguished. Interestingly, other researchers have also found advantages on achievement in general in relatives of bipolar individuals. These findings may support the inverted-U effect, if a subclinical hypomania or other mild affect is what produced the elevated creativity in the healthy relatives of bipolar patients. These results are also consistent with other research findings: (a) that increased creativity is linked to intermediate, rather than high or low, levels of Eysenck's psychoticism variable; (b) of subtle findings of thought eccentricity found in the normal relatives of bipolar patients; and (c) of higher mean scores on a clinical hypomania scale in creative college students, in the work of Schuldberg and others.

Notably, studies of over-inclusive thinking compared bipolar patients and eminent creators in their styles of thinking. Beginning with Andreasen's work in the 1970s, similarities have been found between writers and bipolar patients in particular, though with some key differences. Patients were less likely than the writers to make adaptive use of over-inclusive thoughts. Related research

found that eminent creators, despite having high mean scores on many Minnesota Multiphasic Personality Inventory psychopathology scales, also showed high scores for ego strength.

Conceivably, with treatment, certain mood-disordered people may show not just decreased symptomatology but increased creative productivity. This research underscores the potential value of eccentricity, and the importance of not pre-maturely judging creative people as ill. Unconventional thinking styles do not necessarily mean pathology – indeed, sometimes may be exceptionally valuable.

State Effects: Is a Good Mood a Good Thing?

When asked directly, non-eminent bipolar patients reported greater creativity during mild mood elevations than during episodes of mania or depression. Their creative periods were associated with characteristics of spontaneous exuberance and cognitive facility, including rapid thinking and fluent associations. Eminent artists and scientists gave similar reports, as the great majority had also experienced intense creative periods associated with many characteristics of mild hypomania.

The prominence in a sample of eminent writers of bipolar II disorder, rather than bipolar I disorder, with its more extreme mood elevations, is also notable. Mechanisms for these cognitive, affective, and motivational advantages of hypomania have been proposed. Other studies have found that even in the general, rather than the psychiatric, population, mild mood elevation – say, from watching a comedy film – can directly enhance creative problem solving. Mood elevation may also enhance cognitive style factors that can be relevant to creativity, such as unusual associations and the creative style factor of overinclusion. For example, in classifying things as flat, the over-inclusive person might mentally stretch a little further, and pull in more imaginative possibilities (or some might say loose, or inappropriate ones).

State Effects: What About Negative Mood?

Unipolar patients have reported a heightened sensitivity when depressed. They do not, however, necessarily report advantages ascribed by bipolar subjects to elevated mood states. Despite preliminary evidence that people with a history of depression may show higher everyday creativity if they have a family history of bipolar disorders, one cannot necessarily conclude that it is the episodes of the depression themselves that are conducive to creativity. Rather, it may be associated with sub-clinical hypomanic highs related to a family history of bipolar disorder.

State and Trait Effects: What About the Normal Relatives of Bipolar Patients?

Of great importance, for manic, schizoaffective, and schizophrenic patients, related (though very much muted) forms of thought disorder were found to be more common in their respective first-degree relatives, even those relatives who were not themselves clinically ill. This is consistent with the finding of elevated creativity in, for instance, the normal relatives of bipolar patients, and in depressed individuals with a bipolar family history, and it suggests operation of some subtle cognitive factors associated with the liability for bipolar disorder. In fact, there are particular qualitative patterns of unusual thinking that differentiate patients with mania from those with schizophrenia – as well as tending to distinguish their respective healthier relatives – patterns that might yield higher creative potential in bipolar patients and their relatives. For bipolar disorders, this involves combinatory thinking, with incongruous combinations of ideas and playful confabulation, as described in Philip Holzman and Mary Hollis Johnston's Thought Disorder Index. These patterns involve loosely tied together ideas and often have a playful quality to their production. These styles produce novel combinations of ideas and unconventional perspectives that may – with proper vetting – be valuable in generating innovative solutions to problems that would not occur to other people. Evolutionary Significance

In October 1996, an invitational conference in New York, on *Manic-Depressive Illness: Evolutionary and Ethical Issues*, was convened by Kay Jamison of Johns Hopkins and Robert Cook-Deegan of the National Academy of Sciences. Participants came from around the world to discuss the genetic and environmental factors, social costs, and adaptive value of bipolar disorder. The participants, who included distinguished scientists and clinicians, urged caution, in this burgeoning era of genetic engineering, against any precipitous efforts to remove from the population gene(s) that increase liability for bipolar disorder, given that this liability is complex, not fully understood, and may have creative advantages for individuals and society.

Multiple authors have noted that a link of bipolar risk with creativity (and perhaps also with leadership) could help explain why genes that contribute to bipolar disorders have not been selected against, given the increased rates of mortality and morbidity in these disorders. A compensatory reproductive advantage would presumably help keep bipolar disorders (and genes that help cause them) around. A handful of eminent people, however dramatic their reproductive power, could not maintain bipolar spectrum disorders at a rate as high as 4%–5% of the population. Everyday creativity could be key in this regard. The liability for bipolar disorders must play out in everyday life in order to maintain an adaptive value and reproductive advantage great enough to compensate for the higher mortality associated with bipolar disorder.

Conclusions, Recommendations, and Optimistic Implications of Research

Links Between Creativity and Genetic Liability for Bipolar Disorder

In conclusion, several different lines of careful research have found evidence for a marked association between increased creative potential and genetic liability for bipolar disorder. Some studies have found evidence for elevated rates of artistic creativity in individuals with bipolar disorders, but the research also has found the greatest elevation of creative professions in the bipolar patient's close biological relatives – especially relatives who themselves are healthy and have no mental disorders! In addition, for those eminent artistic creators who do have a full-blown mood disorder, they report that their periods of greatest creativity coincide with episodes of mild mood elevation, rather than with episodes of mania or depression.

Multiple convergent lines of evidence indicate that the association of creativity with bipolar disorder is usually not due to a positive effect of periods of mania and depression; indeed, those periods may tend to be counterproductive for creative work. Rather, research suggests that the creative advantage for some people with mood disorders may lie in the episodes of milder mood elevation. Why might this be so?

Complementary research suggests that several psychological factors associated with milder mood elevation tend to be associated with interest in, and generation, of creative ideas, as well as with work to develop and win acceptance for creative works and ideas. Thus in scientific as well as artistic fields, creative breakthroughs often involve seeing problems in novel ways that have not occurred to others, and that challenge conventional wisdom in the field. Paradoxically, the greatest breakthroughs often prompt criticism, even ostracism, from authorities committed to traditional theories and genre. Picasso's fellow artists initially ridiculed his breakthrough art. Barry Wallace's Nobel-Prize-winning discovery that a bacterium caused stomach ulcers was ridiculed at first. JK Rowling's first Harry Potter novel was rejected by the first several dozen publishers.

Milder mood elevation tends to facilitate not only access to unusual ideas, but also increased energy, ambition, self-confidence, perseverance, and sociability. Those traits are key assets in overcoming resistance to new ideas, persisting despite initial rejections, and selling one's ideas to skeptical "gatekeepers" e.g., editors, patent officers, and gallery owners who decide whether creative ideas are recognized or die with their creators.

Some Optimistic Social and Clinical Implications

The research we have reviewed has several rather optimistic implications. First, the suffering and disability of severe moods are not a "price" one must pay for creative achievements. Second, the finding that milder mood elevation, rather than full-blown mania, is conducive to greater creativity may encourage bipolar patients to take mood-stabilizing medications (Patients' failure to take medication is a major factor in high rates of relapse and hospitalization). Third, links between enhanced creativity and bipolar liability may help reduce stigma and boost morale among patients and their relatives. Fourth, the link may lead families, teachers, counselors, and clinicians to encourage bipolar patients and their relatives to investigate creative jobs and hobbies – to the potential benefit of themselves and the broader society who reap the rewards of creative breakthroughs.

Introduction

Most children grow up with siblings. Do early experiences with siblings promote or discourage creativity? The collective wisdom about siblings is that they do influence each other in many ways, including the development of creative abilities.

Defining Sibling Categories

Birth order and the number of siblings in each family are the most commonly used sibling categories in research and theory. Children who are born first into their families are only children until their first sibling is born and then they become firstborns. Over time, more children may be born until the sibling set is complete and the last child is identified. In research, children whose order-of-birth puts them between the first and last born are grouped together and called middle borns. The number of siblings in the family, referred to here as sibship size, also influences the effects of birth order, not only by determining the number of middle borns in a family, but also by limiting the amount of parental investment available for individual children (Hertwig et al., 2002). In most research and theory, sibling effects have been portrayed as fixed, even though many sibling effects, including those associated with birth order and sibship size, are dynamic during the early years of childhood.

There are other sibling factors that can moderate the effects of birth order and sibship size on outcomes. One moderator is the age difference between siblings. For example, twins have no age gap. They interact almost continuously during childhood and their early experiences together undoubtedly influence their outcomes. In contrast, some siblings are much younger or older than their siblings, providing them with few opportunities for sibling experiences during childhood. Because of variations in age gaps between siblings, sibling effects for twins are likely to be much greater than sibling effects for those with larger age gaps.

Another type of sibling moderator involves gender and the gender composition of the sibling set. This moderator has been found to influence the development of each child's gender identity as well as his or her gender attitudes. Growing up with an opposite gender sibling provides children the opportunity to understand more about the other gender; while growing up solely with siblings of the same gender may intensify gendered attributes. Both age gaps and gender composition are involved in the development of creativity, as described below.

Birth Order, Age Gaps, and Gender Composition

Within the larger body of birth order research and theory, there is a relatively small group of studies about sibling effects on creativity. Much of this literature addresses the issue of whether firstborns are more or less creative than others. Overall, empirical tests aimed at discovering whether firstborns are more or less creative have reported mixed results. Some studies have found that firstborns have lower levels of creativity; while other studies have found that firstborns have higher levels of creativity than others. Still other studies have reported that firstborns are neither more or less creative than the other sibling categories.

Fortunately, one study (Baer et al., 2005) has addressed these inconsistent findings by examining if sibling moderators, such as age gaps, sibship size, and gender composition, can explain the mixed findings about firstborns. Baer et al. wondered whether firstborns with larger age gaps between themselves and their siblings would score lower in creativity than firstborns closer in age to their siblings. The rationale for this possibility was that firstborns with long age gaps would be more likely to be given the duty of caring for younger siblings (Rosenberg, 1982). Such caregiving experiences are thought to facilitate the firstborns' attainment of more adult-like qualities, such as responsibility, but these experiences are thought to inhibit the development of creativity. Conversely,

Baer et al. argued that firstborns with shorter age gaps would be less likely to be given the duty of caring for younger siblings, thereby avoiding experiences that dampen the development of creativity and instead, allowing for more time to engage in childhood play, an experience associated with the development of creativity.

Furthermore, Baer et al. considered whether the number of younger siblings affected the age gap hypothesis. They argued that having more younger siblings would enhance the negative effect of caregiving for firstborns with large gaps, while having fewer younger siblings would enhance the positive effects of sibling play on creativity.

The Baer et al. study involved teams of college students solving real-world problems including human resources issues and new product development. Teams were asked to generate as many creative solutions as possible for each problem. Shortly after completing each set of tasks, participants individually completed a web-based survey in which they rated the creative contributions made by each of their teammates. Each individual's contributions to the problem-solving tasks were evaluated for creativity by his or her teammates in terms of novelty as well as usefulness. Each participant received a composite creativity score, based on the evaluations of their teammates, across two tasks.

With these data, Baer et al. found support for the idea that age gaps and sibship size moderated the creativity of firstborns. Specifically, they found that firstborns who were closer in age to their (smaller number of) siblings had higher creativity scores; while firstborns who were further in age from their (larger number of) siblings had lower creativity scores. This finding demonstrated the relation between age interval and creativity, which has been found in previous research (Gaynor and Runco, 1992).

Baer et al. also wondered about the effect of having more opposite-gender siblings on creativity. Several studies have concluded that more experience with opposite-gender siblings promotes psychological androgyny in children, and this combination of both masculine and feminine attributes is thought to enhance creativity (e.g., Wagner et al., 1993). The results of the Baer et al. analyses supported this expectation. That is, they found that firstborns with more opposite-gender siblings scored higher on creativity than firstborns with more same-gender siblings.

Overall, the Baer et al. findings suggest that firstborns are a heterogeneous group, especially in terms of understanding their level of creativity. Although all firstborns have younger siblings, the distance between the first and later borns, either in terms of age or gender, and the number of younger siblings they have, affect the experiences of firstborns as they mature. These experiences ultimately contribute to their developing varying degrees of creative abilities. Firstborns with short age gaps, fewer siblings, and opposite-gender siblings are advantaged in terms of developing creativity.

Growing Up Without Siblings

Children who are the first child of their parents, but never acquire siblings, are labeled only children. All firstborns are only children for a limited duration during childhood; however, only children are distinct in that they are simultaneously the first and last child within their families. This section will focus on emerging research suggesting that only children exhibit greater capacity for creativity.

Mechanism Promoting Creativity in Only Children

There are several mechanisms potentially contributing to this greater creativity among only children; three are described here. The first involves the fact that one-child parents can invest all their resources, including attention and affection, into supporting their single child's development (Hertwig et al., 2002). Parental investment is thought to promote the intellectual and socioemotional development of children generally, and the fact that only children get more parental investment than other children probably accounts for their greater intellectual abilities and self-esteem (Falbo and Polit, 1986). In turn, these positive developmental outcomes for only children facilitate their expression of creativity (Sternberg and O'Hara, 1999).

The second mechanism facilitating the development of creativity involves the likelihood that only children spend more time alone as they are growing up, giving them more opportunity to become comfortable with, and maybe even develop a preference for, lower degrees of sociability (Falbo and Polit, 1986). Recently, Bowker et al. (2017) found that one type of social withdrawal, which they called "unsociability," benefitted individuals, by enhancing their creativity. Therefore, the greater likelihood that only children spend time alone as children may afford them more opportunity to develop creativity, and if they retain their unsociability as adults, they may retain their advantages in creativity.

The third mechanism involves parents of only children being more likely to promote gender role flexibility, especially for only-child daughters. An early study (Katz and Boswell, 1984) found that parents of one child expressed greater comfort with gender nonconformity for their children than did parents of multiple children, perhaps because their single child must satisfy the parents' desire for both a son and a daughter. In turn, greater gender role nonconformity has been associated with the development of creativity (Baer et al.).

Although any one of these three mechanisms could promote the development of greater creativity in only children, the combination of all three mechanisms for only children probably amplifies these effects on the development of their creativity.

Chinese Only Children

In the past, studies of sibling effects on creativity have either removed only children from their sample, because only children have no siblings, or they have combined them with firstborns, due to the small numbers of only children in their samples. More recently,

however, one-child families have become more common, especially in China, and we now have more only children to study as a separate category in research. Two such studies about only children and creativity are highlighted here.

The first study of Chinese only children and creativity (Yang et al., 2017) was remarkable in that it combined MRI data with assessments of creativity using the Torrance Test of Creative Thinking (TTCT). The TTCT was designed as a measure of divergent thinking, a central aspect of creativity, and it included verbal, figural and auditory tests. The performance of participants was scored along three dimensions: fluency, flexibility and originality. Although scores for each dimension can be considered separately in research, these three scores can be combined to create a total score.

The Yang et al. findings indicated that only children scored higher on one of the three creativity dimensions, flexibility, reflecting greater capacity to shift between conceptual fields. There was no significant difference between only children and their peers with siblings on the other dimensions of creativity.

Furthermore, analyses of the MRI data indicated that parts of the brain associated with creativity had higher volume in only children than in their peers with siblings. Specifically, the MRI results indicated that there were gray matter volume differences between only children and their peers with siblings, in the brain region of the supramarginal gyrus. Greater volume in this region was found to be positively correlated with flexibility scores. Thus, the authors concluded that growing up without siblings in China led to these children having more experiences that promoted the development of the part of the brain associated with some dimensions of divergent thinking.

The second study about only children and creativity considered gender in combination with birth order (Guo et al., 2018). The participants were given two tests of divergent thinking: one involved imagining all the possible meanings of irregular figures and the other involved responses to real-world problems. Overall, the results indicated that only children scored higher on visual imagination (line meaning) tasks than children with siblings. Furthermore, the group with the highest combined creativity scores were only-child daughters.

Guo et al. explained these findings in terms of the effect of China's One-Child Policy (OCP) on the development of children, especially girls with no siblings. The propaganda surrounding the implementation of the OCP emphasized that limiting families to one child would produce high "quality" children who would become the vanguard of China's emergence as a world leader. Educational opportunities were expanded in China so that only children could obtain the advantages associated with greater educational attainment. Several studies have documented that Chinese only children on average scored higher on tests of intellectual ability than did their peers who grew up with siblings (Falbo and Rodgers, 2019).

China has had a long tradition favoring sons over daughters, with parents investing more in the education of their sons, because they expected sons to support their parents when the parents were no longer able to take care of themselves. Daughters were expected to marry into other families and serve the interests of their husband's family. The family planning policy challenged this tradition, forcing parents to accept the fact that they could have only one child, even if that child was a daughter. According to Fong (2004), parents of only daughters responded by pushing their daughters to become academically skilled and emotionally strong, so that they could grow into the role that sons had traditionally taken. Parents of only-child daughters did this by providing their daughters with all the enrichment they could afford, including advanced schooling, music lessons, and foreign language training. Furthermore, not only were these daughters trained to step into roles more commonly taken by men, but they were also expected to exhibit desirable feminine attributes. Thus, only-child daughters were given early experiences that promoted the development of their creative abilities, and therefore, it is not surprising that Guo et al. found that they excelled at creativity.

It is possible that this finding of greater creativity among only children, and only-child daughters in particular, may be limited to China, where the OCP promoted the one-child family as a national policy. While the Chinese policy probably amplified the power of mechanisms that promoted the creativity of Chinese only children, there have been research studies based on Western samples finding that only children were overrepresented among classical music composers (Schubert et al., 1977). Thus, it is possible that only children in general are more likely to acquire creative abilities, due to greater parental investment, spending more time alone as children, and the likelihood that their parents promote greater gender role flexibility in their children, especially in their daughters. More research is needed in order to determine if the advantages of only children, in terms of the development of their creative abilities, are more pronounced in China than other countries, and whether significant only-child effects on creativity can be found in samples from other nations.

Are Sibling Effects Permanent?

Are sibling effects on creativity permanent? Can the assumption be made that only children and firstborns will retain the levels of creativity they developed in childhood throughout their lives? Are middle or last borns destined to low levels of creativity? Based on theory and research about sibling effects in general, the answers to these questions are no, no, and no. The collective wisdom about sibling effects is that they are often found to be so small as to be not significant and when they are found to be statistically significant, they are typically small in size.

Furthermore sibling effects are more likely to be found when research participants are younger, as children, adolescents, and young adults. This is not surprising since siblings growing up in the same household are forced into a situation of sharing their family resources, including parental attention and affection. Consequently, children may develop behavioral tendencies and thinking skills in response to their shared household that result in the development of more or less creativity.

When siblings grow up and leave home, however, sibling effects may become weaker. For example, firstborns who played with their younger siblings, instead of supervising them, may develop high levels of creative abilities, as shown in early adulthood. But, if they are placed in adult roles that allow for little expression of creativity, over time, this new environment and its demands is likely to diminish their creativity. Conversely, middle borns may leave home and find themselves in work environments requiring them to spend more time alone, or alternately, in work environments that allow them substantial time playfully interacting with peers. These experiences may lead to an enhancement of their creative abilities. Because of these new experiences after leaving home, sibling effects on creativity may diminish as individuals mature in middle age and later life. The weakening of sibling effects across the lifespan explains why some researchers have reported finding no significant birth order effects, especially when long spans of longitudinal data are considered, or when other factors, such as socioeconomic status, are included in analyses.

Instead of permanent sibling effects on creativity, we argue that engagement in activities known to promote creativity, such as engagement in intellectual stimulation or spending time alone, promotes the expression of creativity, regardless of sibling status.

Future Directions

To our knowledge, empirical studies investigating the relationship between birth order and creativity have typically employed between-family research designs, which have examined these effects at one point in time (i.e., cross-sectionally) with all participants unrelated to each other. Such research designs usually fail to adequately control the confounding factors relevant to between-family differences, such as socioeconomic status, sibship size, neighborhood context, family dynamics and inherited traits. Such factors are relevant to the development of creative abilities in children and adolescents and yet, they are largely determined by historical and demographic factors outside of the control of researchers and their statistical analyses.

Due to the limitations of these between-family designs, future studies of sibling effects on creativity should consider employing longitudinal, within-family designs. These within-family designs would allow for the examination of sibling effects on creativity within the same family over time. One major advantage of within-family designs is that they may perform better in controlling confounding factors because participants are clustered together within family, limiting the influence of such factors as genetic inheritance. By using longitudinal and within-family research designs, changes in birth order and other sibling factors, as well as changes in creativity, can be observed and evaluated. This approach is likely to yield results that expand our understanding of siblings effects on the development of creativity.

Another approach to advancing our understanding of sibling effects on the development of creativity is to apply qualitative methods to the examination of sibling effects within families. The research results described in this entry were all been based on quantitative studies of sibling effects on creativity. However, another approach, based on smaller samples of families with in-depth qualitative data about each family member, may well provide the types of data and analysis that will advance knowledge of sibling effects on the development of creativity.

An example of a more qualitative approach can be found in *The Pecking Order* (Conley, 2004), a book that combined publicly available information about famous siblings, with the information provided by interviews of siblings from more typical families. As such, this book provides insights into the dynamics of sibling effects, over the course of childhood, adolescence, and adulthood. Conley combined information about genetic influences on individual differences between siblings, describing how these differences are perceived by siblings and parents. He also described the influence of growing up in large families, arguing that some of the strongest sibling effects can be found with larger numbers of siblings. He also addresses the effects of losing family members on sibling effects as well as the effects of gender composition and expectations on children's development. Unfortunately, Conley did not address the development of creativity. However, scholars can use Conley's approach in future books to advance knowledge of sibling effects on the development of creativity.

Other qualitative approaches to research in this area involves more granular data collection from single families, following siblings over time to determine how their experiences at home with each other affects the development of creative abilities. Interviews of siblings within families would be especially informative, particularly if the sample focuses on specific domains of creativity, such as music or media, and there are research questions focusing on perceived obstacles and stimulants to the siblings development of creativity.

Breadth of Attention the number and range of stimuli in the environment or concepts in the associative network attended to at any one time.

Convergent Thinking analytical, controlled, goal-oriented thinking using algorithms and directed towards finding a correct solution.

Divergent Thinking is based on the generation of multiple ideas or the reinterpretation of a problem; relies on the activation of concepts within an associative network.

Scope of conceptual attention defined as the range of activation of mental representations in long-term memory.

Type-1 processing fast, automatic, and nonconscious cognitive processing.

Type-2 processing slow, deliberate processing based in working memory.

Definition of Breadth of Attention

Breadth of attention refers to the number and range of stimuli in the environment or concepts in the associative network attended to at any one time. People exhibiting a narrow state of attention focus on a relatively small range of information and filter irrelevant data from their awareness. Conversely, people having a broad state of attention focus on a large range of stimuli or concepts and tend to be more aware of irrelevant information. The distinction between broad and narrow attention has also been framed in terms of global and local features, or said differently, seeing the forest (broad attention) or seeing trees (narrow attention).

In the field of visual attention research, Navon (1977) asserted that breadth of attention corresponds to the manner in which information is processed: broad, or global attention, corresponds to global-to-local, or top-down information processing, which under normal circumstances is how humans tend to process information. Gestalt psychologists posited that humans process information holistically, a view that gave rise to the global-precedence hypothesis that was widely supported in initial studies. However, later research disputed the inevitability of top-down processing arguing, that initially, information is briefly processed in a bottom-up manner, and that only then, do top-down processes assume control. Top-down processing also influences the size of attentional window, i.e., it can broaden, or narrow attention based on the demands of the environment. Similarly, perceptual processing research has shown a distinction between contextually and conceptually driven processing. Contextual processing is guided by sensory information, which corresponds to a narrowing of attention while engaged in task performance; whereas conceptually driven processing is guided by concepts stored in long-term memory, which corresponds to a broad attentional focus.

Attention and Creativity

Attention is linked to creativity in several ways. Anecdotal accounts from eminent creators reveal that during the creative process many inventive individuals have a difficult time screening out irrelevant stimuli, such as incidental sounds, thereby suggesting that they experience wide attentional breadth while creating. Creative scientists also reported changes in their attentional focus during the creative process. With regards to insight, they described their attention as “diffused” just prior to an insight, and as “scanning” once an insight was achieved. There is also controlled research related to the influence of attention on creative thinking.

Theoretical Considerations

Mednick's influential Associative Theory of Creativity (1962), proposed that a greater amount of creative ideas are achieved through accessing more distant nodes in the associative network. The theory suggests a relationship between the scope of attention and creativity. That is, broader attentional scope should facilitate access to more peripherally located original information, resulting in the higher probability of coming up with more unorthodox creative responses. Mednick proposed that individual differences in the strength distribution of associative responses are responsible for individuals' differences in creativity.

Mednick distinguished between individuals with steep and flat associative hierarchies. Individuals with steep associative hierarchy tend to be restricted to stereotypical responses, i.e., responses high in associative strength. The associative strength of responses to stimuli for individuals with a flat associative hierarchy is more equally distributed, thus increasing their probability of producing a more remotely associated, and therefore less stereotypical, response. Mednick asserted that, "It is among these more remote responses that the requisite elements and mediating terms for a creative solution will be lurking" (Mednick, 1962, p. 223). Contingent on this, individual differences in response associative strength can be viewed as differences in breadth of conceptual attention, i.e., individuals with a steep associative hierarchy can be described as having a narrow scope of attention, and individuals with a flat associative hierarchy can be viewed as having a broad scope of attention (Martindale, 1995). Thus, individuals with a broad attentional scope will tend to produce the least stereotypical, and therefore, most creative, responses. (See Remote Associates)

Mendelsohn (1976) similarly thought that a wide breadth of attention facilitates creative performance. He noted that "the greater the attention capacity, the more likely the combinatorial leap which is generally described as the hallmark of creativity" (p. 366). Mendelsohn viewed attention as an important variable in studying creativity that is independent from intelligence.

In a series of studies, Mendelsohn and his colleagues showed that a wide breadth of attention aided creative performance.

Divergent and Convergent Thinking

Guilford (1956) created a differentiation between what he called divergent and convergent thinking. Divergent thinking usually occurs in an ill-defined problem space, where no specific description of a problem situation is given, and the criteria for an outcome is incomplete or lacking. It is generally characterized by the generation of multiple ideas to a given situation or the reinterpretation of an initial problem. Additionally, there is the presence of a heavy reliance on heuristics and the accessing of remote associates in the associative network. Guilford viewed divergent thinking as a synonym of creative thinking, and as the opposite of convergent thinking. (See Divergent Thinking) He described convergent thinking as a non-creative thinking process geared towards giving the "correct" answer to a well-defined problem. Later, convergent thinking descriptors were expanded to include terms such as analytical and logical thinking and further as controlled processing and the application of algorithms.

Numerous studies found that greater attentional breadth causes increase in divergent thinking scores. Attentional breadth was examined as both a dispositional characteristic and a situationally induced state.

Kasof (1997) found that dispositional breadth of attention was modestly and positively correlated with the creative performance of writing poetry. And further, that creative performance was affected by noise; in particular, noise impaired the creative performance of participants having a wide base-line attentional breadth more so than with those having a narrow breadth of attention.

Kasof proposed a *complexity hypothesis* to explain these findings. Creative tasks are more complex than other intellectual tasks (such as comprehension or memorization), thus they require greater parallel processing (vs. serial processing), and consequently, greater attentional breadth. On the other hand, simpler tasks do not benefit from greater attentional breadth, as these require a narrower attentional focus to only task-relevant cues. Based on this hypothesis, the more complex the creative task, the more beneficial wide attentional breadth.

Indeed, studies found that situationally induced broad attention was related to better performance on divergent thinking tasks. Participants in the broad attention condition showed greater originality than those in the narrow attention condition. Interestingly, in one experiment, simply manipulating the muscular groups associated with broad or narrow attentional focus affected creativity in a similar manner.

Longitudinal research looked at how attentional training programs may change sports creative performance over time. After completion of a six-month training program, creativity was measured using tactical games that incorporated real-life sports scenarios. These narrow and broad attentional programs improved various aspects of creative sports performance: broad attentional programs improved complex task performance, whereas narrow attentional programs improved simple task performance.

Other studies looked more specifically at the relationship between the scope of conceptual attention and creativity. Broader conceptual attention was associated with higher levels of creativity than narrower conceptual attention. Moreover, broader conceptual attention has not been associated with analytic thinking. Yet, the support for the relationship between broader attentional scope and creativity has not been uniform, with some studies detecting only weak or no relationship, suggesting that if a relationship exists, it is likely small.

Some study findings indicated that creativity might be associated with an impaired functioning of the filter of attention. Necka (1999) found that longer reaction time on attention tasks requiring response inhibition was associated with higher divergent thinking scores, particularly when task complexity increased. Thus, participants who scored higher on the creativity measure had poorer attentional functioning indices, i.e., had a weaker filter of attention than less creative participants.

Nęcka attributed the confusing results of selective attention impairment in creative individuals to a susceptibility to “irrelevant” stimuli that are normally ignored or suppressed. These unusual connections may lead to a greater creativity of responses. In terms of broad/narrow attention, filter of attention, that which provides an ability to filter information, implies a narrowing of attention. Thus, participants who exhibited broader attention had better divergent thinking scores, yet, their ability to filter out irrelevant stimuli was reduced.

Conversely, other studies showed a reversed causal relationship between creativity and attentional breadth. That is, they indicated that engaging in divergent tasks, but not analytic reasoning, broadens the scope of attention (Wronska et al., 2018). With this line of reasoning, attentional breadth is adjusted based on the requirements of a task. Specifically, it broadens when working on tasks requiring access to distant associates in the semantic network, such as divergent thinking tasks, and narrows when working on more data driven tasks that require a singular correct solution, such as analytic problems. Similarly, another study found that broad attention facilitated performance in traditional divergent thinking tasks (e.g., an alternative uses task), but that narrow attention aided performance on tasks requiring extrapolation to a novel situation (Tidikis et al., 2017).

Dual-Process Models of Creative Thinking

Later research questioned Guilford’s idea that only divergent idea production begets creative thinking, while convergent thinking has no association with creativity. Recent studies show divergent thinking as a necessary, but insufficient step in the creative thinking. To produce something original and useful, one must not only come up with a novel idea, but also develop that idea into a realized solution. This other, necessary phase of creation is data driven, analytical, and relies chiefly on processes occurring in the working memory.

The binary nature of the creative process has been conceptualized in different terms. For example, most insight problem researchers delineate at least two distinct stages in achieving an insight: the first stage is generative, associated with a search through the mental representation space, and the second is associated with finding a solution based on a formed representation. Similarly, the Genevieve model differentiates between the generative phase, and the exploration and interpretation phase, with the former relating to divergent, and the latter to convergent thinking. The first step in the creative process, during which incubation and preparation occurs, is associated with defocused, broad attention. This stage is characterized by divergent thinking, conceptually driven processing, a search for novel and unorthodox ideas, and new ways of problem representation. The second step in the creative process is characterized by focused, narrow attention and is associated with illumination and verification. This stage is characterized by data driven information processing and convergent thinking.

These two stages work in opposition to one another progressing through multiple iterations during the creative process. Broadening of attention is associated with an exploration stage. When fresh ideas are brought into awareness, attentional focus is broadened to encompass new possibilities, remote, and seemingly unrelated ideas; in short, most research has traditionally linked this stage to divergent thinking and creativity. During the latter, or convergent thinking, stage, which is associated with a narrowing of attention, new ideas that were brought to attention during the previous, or divergent thinking stage, are scrutinized and strictly analyzed. Unworthy ideas are discarded, while worthy ideas are retained. If no solution is found, the process repeats itself until a satisfactory solution is achieved or the individual gives up.

It is worth noting, that these two stages vary dramatically in terms of their correlates, with many correlates having a positive relationship within one stage, while having a negative relationship within the other stage. For example, the first stage is associated with a higher number of ideas produced, while the second stage is associated with a better quality of ideas, originality, and a restructuring of mental representations. Likewise, analytical data scrutinization and data-driven processing are crucial second stage activities, whereas, these activities would be detrimental during first stage processing, when the production of unusual and unorthodox ideas is important.

Another prominent model of creative problem solving (Nijstad et al., 2010) delineates between two opposing cognitive processes involved in the creative thinking. Known as the dual-pathway model, it differentiates between two distinct means of achieving a creative solution: flexible and persistent thinking. Flexible thinking, traditionally linked to divergent thinking, works towards a creative solution through a combination of distantly related ideas, and the easy switching among those ideas. Consequently, broad attentional focus should benefit this flexibility. On the other hand, persistent thinking refers to the focused and structured search of a limited number of ideas. Attentional breadth should not affect persistent pathways. Studies have, indeed, found empirical support for broad attention favorably affecting flexible, but not persistent thinking. Flexibility and persistence were also found to be negatively correlated.

Studies found that processes associated with what traditionally been named divergent thinking relying on System 1 automatic processes, flexible thinking, and activation of the distant nodes in the associative network benefit from broad attentional focus. On the other hand, processes that rely on System 2, persistent thinking, and working memory benefit from the narrow attention breadth (Tidikis et al., 2017). Thus, the relationship between attentional breadth and creativity depends on the types of cognitive processes a person is utilizing.

Thus, different relationship between attentional breadth and creativity may be observed depending on a task a solver is performing.

Variables Related to the Breadth of Attention

Cognitive Factors

How is the attentional breadth related to closely related constructs [such as working memory (WM), or attentional control]? Studies found that wider attentional breadth was related to a greater WM capacity. Such relationship might be driven by the flexible allocation of attention or attentional control that allows for more diverse selection of stimuli. While having a great deal of shared variance with WM, attentional breadth does not relate to the inhibitory control function of WM.

Research also differentiates between two different aspects of attentional breadth—orienting sensitivity and effortful control and, examined their relationship with two differing creativity types—divergent thinking and insight problem-solving. It appeared that differing aspects of attentional breadth relate differently to two types of creative tasks. More specifically, higher scores on orienting sensitivity predicted greater insight problem solving success, but orienting sensitivity's relationship with divergent thinking was much weaker and disappeared altogether after openness to experience and intelligence were controlled for. Effortful control, on the other hand, predicted higher divergent thinking scores, but not insight problem solving performance.

Emotions

Creativity research has devoted a considerable amount of attention towards emotions as a factor having significant influence on the creative process. [Amabile \(1983\)](#) proposed that emotions may influence creativity through two pathways: motivational and cognitive. One way in which emotion may influence cognitive processes is through broadening or narrowing of attentional focus.

Early investigative work into the relationship between emotion and attention established that high negative emotional arousal causes a narrowing of attention. [Gasper and Clore \(2002\)](#) investigated the effects of emotions on global-local information processing. The results showed that participants in a negative mood condition were less likely than those in a positive mood condition to match a figure based on its global features. Similar findings were obtained in a [Fredrickson \(2000\)](#). Fredrickson reasoned that from an evolutionary perspective, positive moods elicit broad attention that facilitates exploration and experimentation. While negative emotions and narrow attention facilitate survival and problem solving, positive emotions and broadened attention promote play and exploration, facilitating an individual's growth.

However, some studies found anxiety to be related to attentional breadth in a curvilinear fashion, with those participants exhibiting the highest and lowest levels of anxiety showing broader attention than those in less extreme conditions, showing that arousal may play an important role in the emotions/attentional breadth relationship. Similarly, [Gable and Harmon-Jones \(2008, 2010\)](#) took arousal into consideration when looking at the effects of emotion on breadth of attention. In their 2008 study, they found evidence that positive affect high in approach motivation reduced breadth of attention. The authors argued that the reason previous studies found otherwise (that positive mood broadens attentional focus) is due to the fact that these studies manipulated positive affect low in approach motivation. Like the results of previous studies, positive mood low in approach motivation increased global attentional focus. The authors explained these results in terms of evolutionary perspective. Positive affect low in approach motivation implies stability and comfort, which fosters a broadening of attention for play and exploration. Conversely, positive affect high in approach motivation implies desired goal pursuit, in which case, the narrowing of attention serves the function of shutting off irrelevant stimuli that might distract from achieving the main goal.

In a 2010 study, Gable and Harmon-Jones found that while negative affect high in motivational intensity narrowed attentional focus, negative affect low in motivational intensity broadened attentional span. They suggested the reason previous research found that negative affect narrows the scope of attention is due to the fact that only negative affect high in motivational intensity was investigated. Different from most other research, the authors used participants' response time, rather than the number of global-local selections as a dependent measure. The results showed that reaction time between global and local targets was larger in the negative (sad) mood condition than in the neutral mood condition. Additionally, participants in the sad mood condition showed a slower response time to local targets, while reaction time to global targets was similar across all conditions. This was taken as evidence of sad photographs causing a broadening of attention. In a follow-on experiment, the effects of high-motivation negative affect (disgust) were examined. Participants in the disgust condition responded faster to local targets than to global targets, thus showing a narrowing of attention. These results suggest that deactivating negative mood states high in avoidance (sadness), broaden attention, while activating negative moods high in avoidance (disgust), narrow attention.

Other research using a dimensional approach (as opposed to discrete) to emotions found an opposing trend of the relationship between negative emotion high and low on arousal, and breadth of attention. Highly arousing negative emotion caused broadening of attentional focus, while negative emotion low on arousal led to narrowing of attentional breadth ([Tidikis et al., 2017](#)).

Personality Variables

Studies investigating affect associated with personality characteristics also found a similar relationship between mood and attention. For example, introversion, a trait usually associated with narrow attentional focus was found to correlate with attention to negative cues, while extraversion, a trait associated with habitually broad attentional focus, was found to correlate with attention to positive cues ([Derryberry and Reed, 1994](#)).

Conclusion

Research indicates support for the relationship between the broad scope of attention and higher creativity scores, particularly when creativity is measured as the number of divergent ideas produced or the originality of ideas. However, to fully appreciate the relationship between attentional breadth and creativity it is useful to consider the differing cognitive processes involved in creative cognition. Greater breadth of attention correlated with higher scores on tasks requiring accessing remote associates in the semantic network, such as divergent thinking tasks. Such relationships appear to be low to moderate. Narrower attentional breadth has been related to better performance on tasks requiring more effortful, analytic, and data driven processing. Other variables may also mediate the relationship between attentional breadth and creativity. The variables that received the most research are cognitive processes, emotions, and arousal.

Childhood trauma encompasses abuse, neglect, and exposure to violence. A more global term, childhood maltreatment, is often employed to capture a range of negative events that threaten optimal development (D'Arcy and Meng, 2015; Felitti and Anda, 2010). Exposure to maltreatment or adversity may lead to injury and/or damage to multiple systems (neurological, physical, psychological, emotional), and in extreme cases, death. Child maltreatment frequently occurs within the family setting; however, children are also at increased risk for victimization in the community (bullying, assault, robbery, kidnapping, trafficking), and within institutions (i.e., church, military, gangs). Behind closed doors, children are vulnerable to abuse inside and outside the family system. For example, teachers, coaches, and medical care workers all have access to children; the unequal power differential may lead to manipulation, coercion, and abuse of minors who are in their charge (Thomson and Jaque, 2019).

The ACE Study

The Adverse Childhood Experience (ACE) study first began in Kaiser Permanente's Department of Preventive Medicine in San Diego. Dr. Vincent Felitti joined forces with the US Centers for Disease Control and Prevention (CDC) under the leadership of Robert Anda. In 1998, the early ACE study results demonstrated strong associations between adult medical problems and childhood adversity (Felitti et al., 1998). In this early study, individuals with four or more types of childhood adversity had a four to twelve-fold increase in health risks for alcoholism, drug abuse, depression, smoking, sexually transmitted diseases, ischemic heart disease, cancer, chronic lung diseases, skeletal fractures, liver disease, and suicide (Felitti et al., 1998; Felitti and Anda, 2010). The overarching findings indicate a dose response relationship between ACEs and health-related disorders.

Findings from ACE studies indicated that the same child may experience multiple forms of abuse and neglect; this intensifies the complexity of their stress responses (psychological, physiologic, and behavioral). For example, many minors who are exposed to physical or sexual abuse typically experience emotional abuse as well. Domestic violence often increases the likelihood of parental separation or divorce. Children exposed to domestic violence also experience more physical and emotional neglect, higher rates of mentally ill or addicted family members, and incarcerated family members (Felitti and Anda, 2010). Exposure to violence also increases when children are raised in communities or nations that are dominated by events such as ethnic cleansing or war (politically or gang motivated). A factor that further increases morbidity and mortality rates is when children are polyvictimized by multiple perpetrators. All forms of victimization may last a short period of time or extend over years.

Prevalence Rates of Childhood Adversity

The prevalence rates for any form of childhood maltreatment vary between studies, in part due to under-reporting in many countries or communities. Studies indicate that the prevalence rate for any single type of maltreatment is 32% (Afifi et al., 2011). According to

the U.S. Department of Health and Human Services, children under the age of three years old are regarded as the highest group to be victimized with a steady decrease in incidents as the child ages. Approximately 10% of children each year suffer at least four or more types of maltreatment. Gender, ethnicity, disability, single parent families, and foster care children are all factors that influence increased prevalence rates, including higher polyvictimization.

In an epidemiology study (D'Arcy and Meng, 2015), exposure to any type of childhood maltreatment increased the odds ratio (OR) for adult depression (OR = 2.03) and anxiety (OR = 2.70). This epidemiology report suggested that more than half the global cases of depression and anxiety are associated with childhood maltreatment. This same odds ratio (1.4–7.9) pattern is evident for childhood maltreatment and other psychiatric disorders such as bipolar disorder, alcohol and drug abuse, attention deficit disorder, suicidality, personality disorders, dissociation, somatization, and PTSD (Afifi et al., 2011; D'Arcy and Meng, 2015). Worldwide, there is a strong association between childhood adversity and multiple disorders throughout all life-stages (Kessler et al., 2010).

Attachment Formations and Developmental Vulnerabilities

Ultimately, all forms of childhood maltreatment interfere with the formation of secure caregiver attachment systems. Exposure to substantial childhood adversity is significantly related to sustained difficulties resolving past trauma and loss experiences as well as increasing the prevalence of insecure and disorganized attachment patterns (Thomson and Jaque, 2019). Parents with a history of high ACEs are more likely to have children with greater behavioral problems. These parents are inadvertently transmitting dysregulated behavioral responses to their children, including higher incidence of attention-deficit/hyperactivity disorder and diagnoses of emotional disturbances (Felitti and Anda, 2010). In addition, parents who are warm and structured promote creativity in their offspring, whereas parents who are coercive and chaotic harm creativity and a sense of autonomy in their children (Moltafet et al., 2018). These attachment-related experiences become internalized and influence behavioral activating or deactivating coping strategies under stressful situations. These internal attachment models deeply influence exploratory and creative behaviors, with secure attachment models promoting exploration and insecure or disorganized attachment models compromising or stifling exploration.

During development, maltreated children and adolescents exhibit difficulties managing academic and social demands; they struggle with emotional and behavioral regulation (Cook et al., 2005). Trauma exposure compromises their academic achievement and constrains cognitive flexibility and creativity during problem solving tasks. Deficits in executive functioning, attention, and abstract reasoning are evidenced. They frequently suffer a myriad of physical illnesses and they are at high risk for re-victimization throughout childhood and adulthood (Turner et al., 2010). Increased exposure rates are directly related to stress-related disorders such as PTSD, depression, personality disorders, as well as behavioral difficulties (Connell et al., 2018). During adolescence, maltreatment history is associated with increased negative behaviors such as non-suicidal deliberate self-harm, maladaptive belief schemas, and greater vulnerability when participating in events that may increase harm, shame, and self-sacrifice. These difficulties are even more pronounced when cumulative childhood adversity includes emotional neglect and emotional abuse. Collectively, these experiences often promote low self-esteem and poor self-concept (Cook et al., 2005).

Alterations in Neurophysiologic Stress Systems

Robust research demonstrates that exposure to childhood maltreatment alters neurobiological stress systems. Physiologic systems responsible for maintaining stability during environmental challenges are activated at a disproportionate rate in maltreated children compared to non-maltreated children (Danese and McEwen, 2012). Unlike homeostasis, allostasis is a physiologic response that detects external and internal challenges required to adapt to extreme demands (Danese and McEwen, 2012). When allostatic processes are continually engaged, structural and functional changes occur in stress-sensitive systems such as the autonomic nervous system, endocrine system, immune system, and neurological networks such as the executive, default mode, and salience networks (McEwen et al., 2012). These structural alterations are even more prevalent in individuals who are exposed to maltreatment in very early childhood. Alterations also occur at the genetic level with polymorphism changes associated with gene by environment interactions; gene methylation is directly associated with children suffering early life stress (Romens et al., 2015).

These neurological and physiologic changes persist and are clearly evident in adults with histories of childhood maltreatment. They have substantially more psychophysiological reactivity during any small or large traumatic reminder. These individuals struggle to manage stressful situations, including relational stressors. The rapid mobilization of the stress systems ultimately increases inflammatory processes, which increases rates of morbidity and mortality. Studies also identified increased pro-inflammatory conditions that result from cumulative trauma, especially childhood maltreatment (Baumeister et al., 2016). In a meta-analysis study, researchers determined that adult individuals who were exposed to childhood trauma had elevated baseline C-reactive protein, interleukin-6, and tumor necrosis factor- α , especially for those with histories of physical, sexual, or emotional abuse (Baumeister et al., 2016). In addition, a dose response to childhood adversity exposure negatively alters the executive cortical network, which compromises executive functioning. Consequently, children and adolescents struggle with emotional regulation, attention shifting, working memory, and organized thinking; these difficulties generally extend into adulthood. These executive functioning deficits are associated with greater PTSD symptom severity and externalizing behavior, a pattern that is even more extreme in polyvictimized individuals (Turner et al., 2010).

Deficits, Protective Factors, and Creativity

Childhood maltreatment is significantly related to difficulties in academic and social achievement, including realizing creative potential. For example, empirical evidence suggests that exposure to conditions of war trauma impedes creative development. Creative children tend to react more negatively to traumatic events; their ability to find creative expression is compromised and as a result, they may react with more hostile oppositional behavior (Knezevic and Ovensik, 2002). As well, very young children who are exposed to maltreatment are at higher risk for difficulties in developing cognitive and attentional processing. This heightened risk factor is directly related to alterations in the developing brain of the maltreated child. These alterations persist into adulthood; consequently, many creative individuals with very early trauma histories may struggle to regulate sensory stimuli and emotional arousal. Sadly, the dose effect of childhood maltreatment increases despair and suicidal thoughts and actions in mid-adulthood. Many of these highly maltreated children struggle throughout their lives to manage depression, anxiety, and interpersonal relationships. Studies demonstrate that creative individuals, in particular poets (See Poetry), suffer more mental illness and have higher suicide rates (Kyaga et al., 2013). Perhaps the factor that is mediating these elevated pathology patterns reported in creative individuals is the dose effect of cumulative trauma.

The subjective importance of *traumatic event centrality* directly influences both trauma-related symptoms and posttraumatic growth (Bernard et al., 2015). Childhood maltreatment may cast a long shadow into adulthood for some individuals or it may be muted with minimal negative outcomes. Efforts to minimize the negative effects of childhood maltreatment are more difficult when cumulative trauma increases, and even more so when there is a history of sexual abuse (Felitti and Anda, 2010). Equally troubling, many highly traumatized children manifest severe dissociative processing. Efforts to emotionally disengage (dissociation) from the hyperarousal states of intense fear often provoke perceptual states of depersonalization or derealization (Thomson and Jaque, 2019). A feeling of non-existence negatively influences the formation of a sense of self-identity. It alters access to autobiographic memory and diminishes optimal performance.

These experiences may also foster the inverse response; they may serve to increase motivation to climb out of these adverse environments and situations (Olszewski-Kubilius et al., 2015). For many talented children, family members or mentors may encourage their talent development. Although socioeconomic resources and stable family structures are optimal, family systems that are marginalized, such as families that are isolated or dissimilar from the social context in which they reside, may be freed from the normative values and conventions ascribed by that community (Olszewski-Kubilius et al., 2015). Children may be encouraged to pursue less traditional paths in order to realize their talents. Likewise, increased family stress, including rejection and neglect, may foster intrinsic motivation to succeed in order to gain acceptance, attention, or love. Children who experience parental loss, authoritative parenting, domestic violence, and other forms of maltreatment may intensify their efforts to succeed, along with building a tolerance for enduring adversity. As well, they may actively seek strategies to overcome their adversity (Olszewski-Kubilius et al., 2015).

Efforts to thrive despite marginality or hostility may be associated with innate giftedness or talent; these challenges may augment tolerance for ambiguity and uncertainty later in adulthood (Olszewski-Kubilius et al., 2015). Growing up in chaotic families and communities, including exposure to polyvictimization, provokes specific attentional shifting processes necessary to survive. Rather than developing skills to inhibit responses, maltreated children and youth must rapidly switch attention from one task or demand to another challenge (Mittal et al., 2015). Their environment is unpredictable and uncertain. This shifting attentional executive functioning survival skill may promote later success in adulthood, particularly in careers that are inherently unstable and require creative adaptive output.

Promoting Creativity and Cumulative Childhood Trauma

Children exposed to multiple forms of trauma require support and trauma-informed care in order to address a myriad of deficits and adaptations. The first step is to provide safety; in ideal situations the child's living conditions should not be fraught with violence and maltreatment (Thomson and Jaque, 2019). In these safe settings, the child's physiologic responses can stabilize; with more physiologic equilibrium greater self-regulation (emotional, behavioral, interpersonal) can emerge. The ability to engage more complex cognitive processing will increase flexibility and creativity, factors that are essential in problem-solving tasks (Cook et al., 2005). A greater sense of self-autonomy can also be nurtured, especially when a relational support group is cultivated.

Psychological processing of the traumatic events is possible once these safety factors are established. Often these conditions can be cultivated within the creative domains such as art, music, dance, and theater, or within sport settings. For example, engaging in the performance of music, regardless of musical genre, promotes self-awareness and self-understanding (Davis, 2010). While engaging in the creative arts or sporting activities, children and adolescents are given safety and an opportunity to acquire creative problem-solving skills. They can learn to regulate intense emotional responses and nurture relationships that promote positive self-appraisal, self-efficacy, self-worth, and self-esteem (Cook et al., 2005). These experiences foster opportunities to interact with companions that share similar experiences. Maltreated children who are offered these opportunities are able to engage in a supportive community; ideally these supportive communities will expand their reach to include others who were exposed to polyvictimization (Connell et al., 2018). Providing maltreated children with experiences of control and mastery offsets the risk of their potential withdrawal from challenging tasks. Often, maltreated children withdraw sooner

than non-maltreated children because they lack adaptive self-regulating skills, hence the need to nurture self-efficacy. Settings that promote creativity can facilitate perceptions of control and mastery; this may counter the uncertainty experienced during a childhood fraught with maltreatment (Mittal et al., 2015). All these experiences provide opportunities to establish a sense of meaning and purpose. By taking action, pursuing choices, or deepening a sense of spirituality, maltreated individuals can derive meaning from the suffering and hardships they endured; finding meaning has the potential to invigorate self-esteem and self-acceptance.

Conclusion

The devastating effects of childhood trauma are evident across all areas of development and persist into adulthood. The effect of exposure to maltreatment is toxic for the developing psychological and physiologic systems of children and youth. Solid evidence verifies the causal mechanisms of early adversity and later impairment. Research findings indicate that many adult diseases are actually developmental disorders that have their origins in early childhood (Turner et al., 2010). Even when children are provided with opportunities to engage creatively, the toll on their psychological and physiologic development is long lasting. Perhaps research studies that demonstrate higher incidences of mental illness (substance abuse, anxiety, depression, bipolar disorder, psychosis, dissociation, and suicidality) within creative populations are failing to account for the toxic strain that may have its origins in early childhood development (Connell et al., 2018). Studies that account for childhood adversity demonstrate that creative eminence is not fully associated with mental illness; rather childhood adversity increases the vulnerability for mental illness and may diminish the potential for creative output (Kyaga et al., 2013).

Healing complex trauma is often enhanced in creative expressive arts programs. Stress reduction is found to be greater among individuals who engage in one or several expressive arts programs (Thomson and Jaque, 2019). For individuals with high cumulative trauma exposure, evidence indicates that participating in the creative process is associated with heightened purpose. These individuals value the opportunity to make meaning while creating, they experience a sense of belonging in the universe beyond the limits of an isolated self, and they endorse a sense of transformational transcendence (Thomson and Jaque, 2019). For individuals with substantial childhood trauma, even when they achieve eminent status within their creative domain, the positive experiences derived while creating remain vital (Thomson and Jaque, 2019).

Introduction

Consider children's creativity and you may be reminded of a cardboard box transmogrified into a space ship, a pillowcase crafted into a super hero's cape, or a magical fort made-up of blankets strewn over strategically arranged dining room chairs. Supply children with crayons, paint, clay, paper, and scissors, and they will experiment and construct fantastical images and playthings. In fact, children will engage in pretend play, improvise songs and dances, tell stories, and make-up imaginary friends often without abandon or the need for 'toys' in such a spontaneous and natural way that it seems it go without question that children are creative. While it is easy to see that children are creative, it is also clear that their creativity is qualitatively distinct from the type of domain-changing creativity associated with eminent artists and scientists such as Beethoven, Maya Angelou, Albert Einstein, and Steve Jobs. In what follows, we address the nature of creativity seen in typical children, the methods for assessing this disposition, and the factors which impede and those that promote children's creativity. We write from the assumption that creativity, like intelligence, is domain-specific ([Gardner, 1983](#)), and that creativity is distinct from intelligence because any intelligence can be used in a more or less creative way.

The Nature of Children's Creativity

The standard definition of creativity focusses on product: a creative individual is someone who produces something novel and valuable within a domain – whether an intangible creation such as a theory, joke, or musical composition, or a physical production such as an invention, literary work or sculpture. This definition clearly refers to the kind of domain-changing creativity we refer to here as Big-C creativity. Although levels of creativity lie on a continuum, investigations of creativity have traditionally distinguished little-c creativity (the kind measured by standard creativity tests) and Big C creativity. Big-C creativity describes revolutionary contributions like Thomas Edison's invention of the light bulb and Picasso's invention (with Braque) of cubism; little-c creativity refers to more ordinary innovations such as repurposing leftovers for a new delicious meal.

Which of these do children demonstrate? Given that one must master a domain – said to take about ten years – before one can change it, then by definition no child can be Big-C creative. Typical children are little-c creators. Even child prodigies cannot be considered creative in the Big-C sense: Mozart's 5-year-old composition, *Minuet and Trio in G major*, was stunning for a 5-year-old, but it did not change the domain of classical music. Blaise Pascal's discovery at age of 12 that the interior angles of a triangle always add up to the sum of two right angles was equally stunning, but did not change the domain of mathematics since this concept had already been discovered. But, Mozart's and Pascal's childhood creativity are qualitatively distinct from the creative play seen in a typical preschool classroom, and this has led to the concept of mini-c creativity. [Beghetto and Kaufman \(2007\)](#) propose distinguishing the creativity of the average child from that of the prodigy (or amateur artist, in their terms) by calling that of the prodigy mini-c.

Unlike the Big/little categories, which focus on creative expression and production, the mini-c category emphasizes creative potential and the creative process; thus, offering a new standard for evaluating children's creativity. Mini-c creativity refers to "the novel and personally meaningful interpretation of experiences, actions, and events," to the "dynamic, interpretive process of constructing personal knowledge and understanding within a particular sociocultural context" ([Kaufman and Beghetto, 2009](#)). The mini-c concept aligns with the Vygotskian conception of creative development, which posits that all individuals possess creative potential that begins with an "internalization or appropriation of cultural tools and social interaction ... not just copying but rather a transformation or reorganization of incoming information and mental structures based on the individual's characteristics and existing knowledge" ([Moran and John-Steiner, 2003](#), p. 63). The mini-c category underscores the value of recognizing creative aspects associated with

the 'beginner's mind' like openness to new experiences, active observation, and willingness to be surprised, and explore the unknown (Richards, 2007). The mini-c category offers a level of specificity that can allow children's creative interpretations and ideations, as well as the associated behaviors and attitudes, to be recognized and nurtured by parents and educators (Kaufman and Beghetto, 2009). Although there has been some effort to develop a systematic coding frame for micro-level measurements of creativity (described later in this chapter), we do not yet have a standardized valid and reliable way of assessing mini-c creativity.

The Assessment of Children's Creativity

In 1957, the Soviet Union beat the United States into orbit by successfully launching Sputnik, the first artificial satellite. In response to this defeat, American psychologists developed a wide variety of tests to assess children's creative potential, specifically in science and math. Ever since, a plethora of tests have become available for assessing children's creativity at the level of the person, the creative product, and the process. A review of the literature on children's creativity shows that 80% most of studies employ measures on the level of the person or the product (Kupers et al., 2018). Clearly, more research is needed on the creative process.

Divergent thinking tasks are commonly used as indicators of creative potential, and most measures of children's creativity have focused on ideational fluency in which participants must generate as many responses as they can to a particular stimulus. An example of such a task is the Alternative Uses Task where participants are asked to list as many uses as possible for a common item. Responses are scored in term of originality (as compared to responses from other children), fluency (number of responses), flexibility (number of different categories), and elaboration (amount of detail).

The most widely used assessment of divergent thinking is the Torrance Tests of Creative Thinking, which includes a verbal section (Thinking Creatively with Words) consisting of six activities (asking, guessing causes, guessing consequences, product improvement, unusual uses, unusual questions, and just suppose) and a nonverbal section (Thinking Creatively with Pictures) consisting of three figural activities (picture construction, picture completion, and lines/circles). As is the case with the Alternative Uses Test, scores on the Torrance are based on fluency, flexibility, and originality.

Unlike the Alternative Uses and Torrance Tests, which are domain-general assessments of creativity, the Evaluation of Potential for Creativity is used to assess domain-specific divergent and convergent thinking via both verbal and graphic tasks appropriate for elementary through middle school students. The Evaluation of Potential for Creativity is domain-specific, with versions for artistic, literary, social, math, science, and music creativity (Barbot et al., 2011).

Despite their popularity, some creativity researchers have questioned the usefulness of divergent thinking tasks. Simonton (2003, p. 216) expressed concern that "none of these suggested measures can be said to have passed all the psychometric hurdles required of established ability tests. For instance, scores on separate creativity tests often correlate too highly with general intelligence (low divergent validity), correlate very weakly among one another (low convergent validity), and correlate very weakly with objective indicators of overt creative behaviors (low predictive validity)." Although new approaches to the assessment of divergent thinking have been proposed (e.g. top-2 scoring method, in which participants are asked to select their two most creative ideas, which then are evaluated for creativity; Silvia et al., 2008), these evaluations are still just snapshots of creativity that do not capture in real-time the core of creativity, namely the creative process.

Alternatively, Kaufman and Beghetto (2009) suggest self-assessments and microgenetic methods as more naturalistic and informatively rich approaches to pencil-and-paper measures of creative potential, argued to better illuminate the developmental process of children's creativity (mini-c). Self-assessments are useful because they require students to reflect on their own creativity, and thus can reveal how children think about their creativity. The microgenetic method combines close observations (typically video recorded) of children as they progress through developmental stages, and repeated measurements (such as asking children for immediate retrospective explanations of their thoughts and actions) over the course of time. This method has been previously used to study children's learning (Siegler, 2006), and could provide a detailed illustration of the development of a child's creativity by allowing researchers to identify and examine dynamic microlevel changes in psychological structures. Five specific dimensions can be examined through the microgenetic method: the path of change (is the change qualitative or quantitative?); the rate of change (is the change sudden or slow?); the breadth of change (is the change domain-specific or generalizable across domains?); the variability of change (how variable is a person's behavior across similar tasks within a domain?); the source of change (what do the changes in behavior, such as strategy use, suggest about the source of change?; Siegler, 2006). Researchers interested in using the microgenetic method to study children's creativity, could employ the coding system proposed by Kupers et al. (2018) which captures the two core components of creativity – novelty and appropriateness – on an ordinal four-point scale at each moment during the creative process. The coding frame follows three steps: first, researchers must determine the unit of measurement (the level of detail in which they wish to study the creative process), and they then code the units in terms of novelty and appropriateness. This measure is a preliminary and not yet validated, but could well serve as the state of the art in children's creative potential assessment by providing a fuller picture of what is provided by narrower, standard psychometric approaches.

The Development of Children's Creativity

Elsewhere, we have proposed that artistic development in children follows a U-shaped curve (Gardner and Winner, 1981), with preschool children's processes and product similar to those of adult artists, followed by a period between childhood and adulthood

characterized by literalism. Thus, children's drawings are at first playful, joyful, and unconcerned with the conventions of representation or realism. By middle childhood their drawings become more stereotyped as they master the conventions of the graphic domain and focus on the rules of realistic representation. By late adolescence, at least among those children who will become artists, conventions are now broken. Thus, the preschool child is pre-conventional; the adult artist is post-conventional. Most adults however never emerge from the literal stage. This three-stage model has been shown to fit both the development of drawing and of non-literal language use ([Gardner and Winner, 1981](#)).

We can draw a connection here to the stages of children's creativity: it has been argued that young children are more creative than (typical) adults. Both Pablo Picasso and John Lennon shared the belief that artistic impulse is strongest in the early years of life and often attenuates as a child matures. This sentiment is echoed in the most watched TED talk of all time titled "Do schools kill creativity?" in which educationalist Sir Ken Robinson argues that "we don't grow into creativity, we grow out of it." In fact, a longitudinal study examining creative capacity across childhood showed that when kindergartners were tested, 98 percent scored at the genius level in divergent thinking on the test employed by the National Aeronautics and Space Administration to select innovative engineers and scientists. The same children were re-tested when they were ten and 15 years old, at which point only 32 percent and 12 percent scored as high, respectively. Moreover, only a mere two percent of adults over the age of 25 demonstrated the same high level of creativity as the five-year-olds in the study ([Land and Jarman, 1992](#)). Kim (2011) found a similar trend of diminishing creativity with age; her analysis of the Torrance scores of 272, 599 kindergarten through 12th grade students and adults between 1974 and 2008 showed that since 1990, even as IQ scores grew higher, creative thinking scores have significantly declined, especially in kindergarten through third grade. These findings reveal that children have, over the years, become less able to generate many ideas, generate novel ideas, and elaborate on these ideas, and have become less intellectually curious and less open to new experiences.

Kim's study is based on the assumption that creativity is domain-general. However, a study by [Weinstein et al. \(2014\)](#) reported a decline in the creativity of adolescent writing since 1990, along with a rise in the creativity of adolescent visual artworks (as assessed qualitatively rather than by a standardized creativity test). Findings like Kim's as well as Weinstein et al.'s underscore the need to discover the factors that impede (as well as promote) children's creativity.

Factors Affecting Children's Creativity

This loss of creative potential may result from external factors such as pressure to think and behave according to conventions. This loss might also reflect internal factors such as an increase in reasoning skills and executive functions, which also takes place around this age and which may interfere with the free play of imagination.

Externally Caused Factors

One factor that may be impeding children's creativity is the emphasis on rote learning and standardized testing in schools. This focus stands in direct contrast to play. Beginning at about eighteen months, children engage extensively in pretend play, which may serve as practice for the types of imaginative thinking observed in the creative activities and innovations of adults. Play – whether physical, constructive, imaginative, dramatic, or games with rules – is the primary way that humans learn to understand and experience the world. Yet, instead of prioritizing play, the focus and investment on narrow high-stakes standardized testing in schools has left little time or resources for children to employ their creative potential.

A second factor that has been shown to impede creativity in children (as well as adults) is the extrinsic motivation to get a good grade or win a competition. Research has shown that intrinsic motivation is important for creativity, and that extrinsic motivation is a strong impediment.

A third factor may be parental focus on obedience. Being creative requires taking risks. Creative people innovate novel ideas that may be criticized, ridiculed, or ignored by audiences. In fact, creativity is most strongly associated with social risk-taking (i.e. the willingness to challenge norms), which can be an ostracizing experience. If creativity is to develop, it must be encouraged by caring others in a supportive environment. However, research shows that child obedience is valued over independence by parents in nations where poverty and lack of education prevail. Given that creativity necessitates risk-taking and sometimes rule-breaking, it follows that children living in poverty may face an impediment to their creativity from parenting practices that foster obedience and conformity. Additionally, children from low-income households often attend Title 1 schools – institutions with large concentrations of low-income students that adhere to rigid classrooms and high-stakes standardized tests. Furthermore, the No Child Left Behind Act and Common Core Standards Act caused schools to focus their resources on subjects like reading and math to achieve high scores on statewide standardized tests. As a result, arts classes (which are more likely to develop creativity than classes requiring rote learning) received less funding, leading to fewer arts opportunities in schools. The consequence of these budget cuts is less detrimental for students who live in affluent communities and receive the benefits of arts education through extracurricular programs, which may be cost-prohibitive for low-income children.

External factors may also be used to *promote* creativity – specifically a focus on play. Research has shown that children who participated in flexible play experiences showed significantly greater creativity on the Torrance than children participating in highly structured play experiences. Consistent with these results, [Garaigordobil and Berrueto \(2011\)](#) found verbal and graphic-figural creativity of preschoolers, and 10- and 11-year-olds improved significantly from a weekly 75-min or two-hour play session throughout the

academic year. Dansky and Silverman (1973) found that children who were given the opportunity to play with objects gave significantly more uses for those objects than did children in the control condition who did not get a chance to play with the objects beforehand; findings from this study highlight the importance of play as a means of encouraging divergent thinking and reducing functional fixedness (a cognitive bias that limits one's mental representation of an object to that object's typical use).

Internal Factors

An internal factor that has been shown to impede creativity in adults is strong cognitive control. Cognitive control, the ability to limit attention to goal-relevant information, subserves higher-order cognitive functions such as reasoning, attention, planning and organization. Counterintuitively, deficits in these functions have proven advantageous in certain contexts: low cognitive control means less filtering of attention, and such unfiltered attention leads to novel solutions in creative problem solving contexts. For example, young children have weaker cognitive control than do older children, and have also been found to solve creative problems better than older children (German and Defeyter, 2000). In addition, when cognitive control is compromised because of Attention Deficit Hyperactivity Disorder, age, fatigue, intoxication, and disruption of the pre-frontal cortex due to transcranial direct current stimulation or lesions, the ability to "think out of the box" is enhanced. In short, impaired cognitive control in adults is associated with heightened creative thinking, and we are now investigating the possibility that children with low cognitive control (often a result of the stress of poverty) have enhanced creative abilities. Paradoxically, thus, schools' attempts to enhance cognitive control may have the unintended consequence of dampening creative potential.

Conclusion

In this chapter, we reviewed research showing that while children demonstrate little-c creativity across a variety of domains, a focus on mini-c may help to shed light on the *process* of children's creativity. A decline of creativity in mid-childhood, "the fourth-grade slump," may be a consequence of education systems and child rearing practices that value obedience over play.

As globalization and technological developments accelerate, we face unprecedented social, economic and environmental challenges. In order to successfully navigate the uncertainties of the future and solve unpredictable problems, our children will need to develop their creative capacities. Accordingly, the Organization for Economic Cooperation and Development, United Nations Educational, Scientific and Cultural Organization, and Partnership for 21st Century Skills have identified creativity and innovation in problem-solving as fundamental employability skills. Considering that corporate executives and public sector leaders worldwide cite creativity as the most important leadership quality for success in business, today's children would be best served by rearing practices and curricula that nurture the development of their creativity.

Climate

Creative work, the production of original, high quality, and elegant solutions, to complex, novel, ill-defined, or poorly structured problems requires people to invest substantial resources, both cognitive and emotional resources, in their work. In fact, prior studies have shown that motivation to solve the problem at hand, confidence in one's ability to solve the problem, and the relevance of solving the problem to one's personal and professional self-image, or identity, all influence people's investment of cognitive resources in solving creative problems—and, their subsequent success in solving creative problems.

The importance of motivation for creative work cannot be disputed. One must remember, however, that people must also make a decision to invest scarce resources in creative work. Often, people's perception of the environment in which creative work is to occur leads them to believe that a creative problem cannot be solved or, if solved, their efforts will not be rewarded. Thus, people make a decision based on their perceptions of their work environment as to whether they will invest resources in solving creative problems.

Recognition of this point has led to an interest in the nature of the environment that encourages people to undertake creative work—solving the kinds of problems that call for creative thought. In the present effort, we will examine the various models that have been proposed which seek to describe the kind of work environments that encourage, or discourage, creative thought. This chapter examines how the variables specified in these models influence creative performance and the variables that act to moderate these effects. Finally, we will consider how institutions might go about establishing a climate likely to encourage people to invest in creative problem-solving.

Psychological Climate

At first glance, it seems rather easy to identify attributes of people's work environment. One might just observe the environment, however, people see, and attend to, different aspects of their work environment. The environment one person "sees" may not be the same as the environment other people "see". Thus, in a work group, while some people might endorse the statement "people in my work group are rewarded fairly", others might not endorse this statement. Put differently, the environment is in the eye of the beholder. Accordingly, many scholars have argued that climate must be measured through people's perceptions of their work environment.

[☆] *Change History*: August 2019. Michael Mumford updated the text throughout the article.

This article is an update of T.L. Friedrich, C.K. Stenmark, M.D. Mumford, Climate for Creativity, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 208–213.

This apparently straightforward observation, however, raises three key questions bearing on any study of climate. First, what attributes, or dimensions, of the environment are people perceiving? Second, what is the significance of these perceived attributes of the environment for people's performance? Third, how do we know it is really the environment people are perceiving – might it just be their personality?

There is a straightforward answer to this third question. James (1982) has argued that climate, an environmental event, can be assumed to exist when multiple people agree about the existence of this event. Thus, if people working in a common environment, or on a common task, all agree an event occurs, we attribute their responses to a question, for example, "safety procedures are clearly described" to the environment—not their unique personality.

The need to establish agreement with respect to attributes of a certain work environment has another noteworthy implication. An explicit definition must be provided as to who might, or might not, share a common work environment. Thus, a study of service climate at a telecommunications firm may have little to say about service climate at an energy firm. Moreover, agreement may not be constant across different levels in a firm (e.g. managers versus workers) and it may not be constant across different units within a firm where the same work is occurring.

Assuming one can demonstrate agreement, a new question comes to fore – agreement with respect to what? Environments, including the environments people perceive, are complex, multifaceted, entities. Thus, Schneider (1980) talks about service climate and Zohar (2010) talks about safety climate. Each model is examining agreement with respect to certain attributes of the work environment where these attributes of the work environment are held to impact certain outcomes, or certain forms, of the performance of interest. Thus, a key question in all climate studies is, exactly what are the attributes of the environment that are relevant to the outcomes of interest?

Of course, our foregoing observations broach a new key question of concern in studies of psychological climate. If more, or less, of an environmental attribute is perceived by people working in an environment, is this attribute related to the performance of interest? This question, moreover, may be extended to the conditions under which these relationships are observed—moderators, or conditions under which, climate attributes are related to the outcomes of interest.

When attributes of the environment impacting performance have been identified and the conditions under which these relationships are observed have been specified, we can identify actions to take on this environment to bring about certain outcomes. Environments are not fixed but can be changed. In fact, the desire to establish work environments likely to encourage creative problem-solving underlies our interest in creative climate.

Climate Models

Of course, many attributes of the environment might act to influence creative problem-solving. Thus, if one believes autonomy is important, one might ask people to indicate whether "people in my workplace have the freedom to pursue ideas they believe to be important". If one believes peer support is important, one might ask people to indicate whether "my coworkers will provide me with ideas to help me solve problems I am encountering in my work". If one believes resources are important, one might ask people to indicate whether "we have the equipment needed to pursue work on our projects".

The foregoing questions not only illustrate the types of questions asked in creative climate inventories, they also point to a broader issue. Exactly what attributes of the environment are of concern in accounting for creativity? And, over the years, multiple models of creative climate have been proposed with different theoretical models being used to specify different attributes of the environment that might contribute to creative problem-solving. Broadly speaking, these various models appear to be based on one of two meta-theoretical frameworks: 1) psychological and 2) organizational.

In the psychological model, environmental conditions which would encourage an individual to invest resources in creative work are used to specify climate attributes. Thus, Amabile et al. (1996) argued social supports are crucial for such investments, leading them to hold that perceived work group support, challenging work, supervisory encouragement, freedom, and sufficient resources, among other dimensions, would contribute to creativity. Ekvall and Ryhammar (1999) take a different approach, arguing a creative environment is an environment which allows people to express their creative personality. Thus, they propose climate dimensions such as playfulness and humor, trust, freedom, challenges, and risk-taking among other dimensions.

In the organizational model, attributes or specific features of the work environment are used to specify the attributes of concern. For example, Anderson and West (1998) argued that in the "real-world", most creative work occurs in teams. Their understanding of team interactions was used to propose a climate model which includes four attributes: 1) participative safety, 2) support for innovation, 3) challenging objectives, and 4) task orientation. Abbey and Dickson (1983), in contrast, argued creative work occurs in new product development efforts and the characteristics of new product development efforts led them to propose climate dimensions such as cooperation, reward system, status polarization, structure, and flexibility.

Of course, other psychological (e.g., environmental attributes contributing to creative self-efficacy), and organizational (e.g., environmental attributes contributing to organizational learning) attributes might be used to specify still other climate models. By the same token, these models do specify certain common attributes, attributes of the environment, consistently held to contribute to a climate for creativity.

Hunter et al. (2005) reviewed the various models of creative climate, both psychological and organizational models that have been proposed over the years. In this review, explicit operational definitions of each climate variable were obtained. Judges then classified those climate variables into general categories with high levels of inter-judge agreement being observed in final category assignments. They identified 14 attributes, or dimensions, commonly found in models of creative climate including 1) positive peer group, 2) positive supervisory relationships, 3) adequate resources, 4) task challenge, 5) mission clarity, 6) autonomy, 7) positive

interpersonal exchanges (e.g., trust), 8) intellectual stimulation, 9) top management support, 10) rewards provided, 11) flexibility and risk-taking, 12) production emphasis, 13) participation, and 14) organizational integration. This 14-dimensional model of creative climate was found to account for more than 90% of the dimensions proposed in earlier models of creative climate.

These environmental attributes allow items, or markers, of each environmental attribute to be formulated—for example, “my colleagues provide useful feedback on project work” or “all members of my work group are encouraged to express their ideas”. When multiple environmental markers of each dimension are identified, adequate internal consistency coefficients are obtained. Moreover, members of work groups agree in how they describe their environment. And, finally, factor analyses show the targeted dimensions, in fact, are those that emerge in examining the relationships among markers and climate dimensions.

Climate and Performance

A key issue remaining, however, is whether differences in people’s exposure to those environmental attributes are positively related to creative performance. In all, some 42 studies have examined the relationships between people’s descriptions of their work environments on these dimensions and subsequent creative performance. Hunter et al. (2007) conducted a meta-analytic study to examine, across studies, the impact of these environmental attributes on creative performance.

The first question, of course, is whether climate perceptions, in general, across all climate dimensions examined, are positively related to creative performance. It was found a more positive climate, in general, was positively related to creative performance yielding a Cohen’s d of 0.75—note d ’s below 0.40 are considered small, d ’s between 0.40 and 0.60 reflect an effect of moderate impact, and d ’s above 0.60 a sizable positive effect. Notably, it was found these effects held when both objective indices, for example—patent awards, and subjective evaluations of creative performance, for example—superior’s appraisals of creative work, were used as the measure of creative performance. Thus, the impact of climate on creative performance evidences good cross-criteria generality.

Of course, one question that might arise with regard to these relationships is whether they are conditioned by certain features of the study design in use—a question of internal validity. Hunter et al. (2007) also coded the studies under consideration with respect to various features of the design employed such as sample size, location of publication (peer or non-peer reviewed), and use of a standardized climate measure or an in-house, locally developed, measure. Broadly speaking, the findings they obtained indicated that the predictive value of climate measures in accounting for measures of creative performance generalized across these study design considerations with two notable exceptions—first, if the study was obtained from a peer-reviewed ($d = 0.86$) as opposed to a non-peer reviewed publication ($d = 0.59$) and if a standardized climate inventory was employed ($d = 1.00$) as opposed to a locally developed, “in house”, inventory ($d = 0.63$).

Given the generality of the impact of climate measures on creative performance, a new question comes to fore—a question of some importance to students of creativity. What climate dimensions, what attributes of the person’s work environment, exerted the strongest effects on creative performance? To address this question, Hunter et al. (2007) asked judges to assign each climate dimension to one of the 14 general climate dimensions described earlier and Cohen’s d ’s were obtained for each dimension.

The findings obtained in this analysis indicated that all 14 climate dimensions were positively related to subsequent creative achievement producing Cohen’s d ’s between 0.48 and 0.91 across the 9 to 30 studies where this dimension was examined. Although other climate dimensions might exist that influence creativity, it seems clear these 14 dimensions, in fact, do influence creative performance.

However, not all these dimensions were equally important. The seven dimensions producing the strongest relationships were 1) positive interpersonal exchange ($d = 0.91$), 2) intellectual stimulation ($d = 0.88$), 3) task challenge ($d = 0.85$), 4) flexibility and risk-taking ($d = 0.78$), 5) top management support ($d = 0.75$), 6) positive supervisory relationships ($d = 0.73$), and 7) positive peer group ($d = 0.68$). The seven dimensions producing the weakest relationships were 1) autonomy ($d = 0.48$), 2) adequate resources ($d = 0.51$), 3) rewards provided ($d = 0.55$), 4) production emphasis ($d = 0.59$), 5) organizational integration ($d = 0.62$), 6) participation ($d = 0.62$), and 7) mission clarity ($d = 0.61$).

These findings, taken as a whole, point to the key characteristics of a creative work environment. A creative work environment is one where people are presented with challenging, intellectually stimulating assignments where they are encouraged to take risks under conditions where they have support—support from peers, supervisors, and top management. Autonomy, resources, rewards, and participation although helpful, are less important than intellectual challenge and support.

Moderators of Climate

Having shown climate perceptions are strongly positively related to creative performance, a new question arises. What attributes of the people, or the context in which the work is being done, act to moderate the relationship between people’s perceptions of their work environment and creative production. One key variable in this regard is the professionalization of the workforce and management of workers with respect to professional practices. In keeping with this observation, Hunter et al. (2007) found that climate exerted stronger effects on creative achievement when climate’s impacts were studied in professions (e.g., engineering, medicine) as opposed to non-professional (e.g., sales, management) occupations. These effects appear to arise both because professionals are expected, as part of their work, to generate new ideas and viable creative problem solutions while they are given some discretion

as to how their work is to be completed. When professionalization, idea generation, and discretion with regard to how work is to be completed are all high, one should expect climate perceptions to have a stronger impact on creative performance.

Another set of moderators that act to condition the impact of climate perceptions on creative performance may be found in characteristics of how teams work together in solving creative problems. Broadly speaking, attributes of teams that act to induce conformity seem to diminish the effects of climate on creative achievement. Thus, high interdependence, substantial cohesion, and strong shared mental models for understanding the problem at hand all seem to act to diminish the effects of climate on creative achievement. Not all team level variables, however, necessarily inhibit the impact of climate on creative achievement. Teams that are reflexive, meaning that they think about why actions worked or did not work, result in climate perceptions having stronger, not weaker, effects on creative achievement. Along somewhat different lines, when team members come from a number of different professional backgrounds, functional diversity, climate perceptions have been found to exert stronger effects on creative achievement.

Creative work, moreover, requires resources and access—access to others and access to institutional decision makers. In fact, prior work indicates that active external communication and diverse networks of contacts contribute to creativity. More centrally, information access, and the need for access to a diverse pool of information, seems to strengthen the relationship between creative climate and subsequent creative achievement. Along similar lines, a lack of resources, time, equipment, and money, can inhibit creative achievement. Again, more centrally, the availability of resources has been found to result in a stronger relationship between creative climate and creative performance.

Sharfman and Dean (1991) have characterized institutional environments with respect to four key variables—capital intensity, turbulence, competitive pressure, and production pressure. Hunter et al. (2007) examined how these variables act to moderate the impact of creative climate on subsequent creative achievement. They found that capital intensity, the need to protect extant investments, acted to attenuate the effects of creative climate. However, the effects of creative climate on subsequent creative achievement became stronger when there was substantial turbulence in the technical environment and intense competitive and production pressure.

These observations are noteworthy because they paint a rather compelling picture of when a creative climate must be established to ensure creative production. When a team of diverse professionals is working in a technically turbulent arena with adequate resources but under intense pressure where conformity is neither desired, or enforced, in the approaches to be taken to problems, then, under these conditions, creative climate will have an especially strong relationship with the production of creative problem solutions and the production of innovative, new, products.

Establishing Climate

James et al. (1990) have shown that the actions taken by leaders are the most powerful influence shaping peoples' perceptions of climate. In keeping with this observation, Isaksen and Akkermans (2011) have described the many actions that might be taken by leaders to improve climate perceptions among those doing creative work. For example, leaders can encourage all team members to voice their ideas. Leaders should expressly recognize the creative accomplishments of team members. Leaders must encourage risk-taking, the pursuit of new ideas, and not punish team members if their ideas do not work out.

Although these, and other actions, by leaders are important to establishing a creative climate, Mumford et al. (2002) argued leaders play three other key roles in establishing a viable creative climate. First, it is the leaders of creative teams who acquire top management support, and requisite resources, for creative efforts—both noteworthy influences on creative climate. Second, leaders establish, and model, appropriate interactions among team members and leaders' modeling of appropriate interaction patterns has a noteworthy impact on peer support. Third, leaders establish the missions to be pursued by teams, and provide team members with technical feedback regarding their work. Thus, leaders establish the challenge confronting teams and help shape an intellectually stimulating environment—and, as noted earlier, both challenge and intellectual stimulation are two of the more important dimensions contributing to perceptions of a creative climate and creative performance.

Leaders and team members, however, both contribute in another way to establishing a viable creative climate. When team members are engaged in the task at hand, active intellectual exchange of ideas and technical, albeit not personal, critiques of ideas will emerge. And, this active, often critical, albeit supportive, intellectual exchange appears to be a key influence on establishing a creative climate. Such exchanges not only ensure the deep criticism found to contribute to creative problem-solving, they also build a sense of creative self-efficacy.

Yet another way one might go about establishing a creative climate is to stress the value of learning with respect to the fundamental concerns at hand—learning that may emerge as much from failure as success. By stressing learning, of course, risk-taking and flexibility are likely to be perceived as noteworthy aspects of the work environment. Moreover, actions that encourage a learning orientation in teams also contribute to feelings of psychological safety. Carmeli et al. (2010) have shown that feelings of psychological safety are a key variable contributing to performance on creative tasks.

Conclusions

Our foregoing observations point to a broader conclusion of some practical significance. The study of creative climate is of substantial practical value because it tells us something about how institutions should seek to manage those it is asking to pursue creative work. Establishing an environment that people perceive as challenging, intellectually stimulating, and supportive is apparently one

key mechanism by which institutions can encourage creative achievement. In fact, when professionals are asked to work on complex, new, or emerging problems, the problems encountered in turbulent environments where production pressure is real, climate perceptions become an especially important influence on subsequent creative achievement. We hope the present effort provides an impetus for future work intended to identify the most effective ways of establishing the kinds of work environments most likely to encourage creative achievement.

The Construct of Cognitive Style

Cognition embraces the whole spectrum of human information processing, including perception, memory, language, learning, thinking, problem solving, and creativity. Systematic individual differences in such modes of information processing have been construed as dimensions of thinking, learning and intellectual styles.

The term 'style' designates a preferred way of doing things. Hence, cognitive style can be defined as consistent individual differences in the ways people prefer to organize and process information. A number of style theories and operational definitions of cognitive style exist. They have focused on a person's typical mode of cognition as reflected in: his or her main dispositions in *perception*, the organization of information in *memory*, the preference for different kinds of general *problem-solving strategies*, the speed and accuracy of *decision making under uncertainty*, the preference for different types of *problems to solve*, etc. Some of these distinctions describe preferences for different approaches to dealing with the challenges involved in creativity.

While such concepts may appear fairly straightforward, the construct of cognitive style has nevertheless been associated with several problems. The more important of these can be grouped into seven major issues.

First, most style researchers have made a distinction between cognitive styles and cognitive abilities. While cognitive styles are defined as describing *how to*, or in what way we process information, cognitive abilities are defined in terms of *how well* we process information. Cognitive abilities capture how much, how well, or how accurately we process visual, semantic, or numerical stimuli. They are rooted in structural conditions that do not leave much room for choice. In contrast, cognitive styles describe differences in preferences to process information in certain ways and are anchored in functional conditions that provide more room for choice in, for example, the types of general strategies we tend to employ when working on problem solving tasks. Cognitive style may also determine whether we primarily perceive wholes or parts in dealing with tasks of problem solving, learning or creativity.

[☆] *Change History*: September 2019. Øyvind Lund Martinsen updated the text throughout the article.

This article is an update of Ø.L. Martinsen, G. Kaufmann, A. Furnham, Cognitive Style and Creativity, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 214–221.

Lack of, or low, correlation between style and ability has commonly been seen as a necessary condition for a style construct to be valid as the two should be related. Certain tasks suit certain styles: brighter people may be able to adapt their style to suit the nature of the task. Further, preferences possibly grow out of abilities. Thus, a facility with numbers may lead to a preference for convergent thinking, while a facility with words may lead to a divergent thinking style. Not all the postulated style constructs have, however, controlled for influences from abilities. Some style constructs have also been shown to have very high correlations with measures of abilities, which puts them in serious jeopardy in terms of fundamental construct validity – that is the two are essentially indistinguishable.

Second, there is the issue of the relationship between cognitive style and personality. Thus, dispositions based on the traits may influence us toward using certain modes of information processing, unless the task demands in the situation ‘forces us’ into other modes of processing. For the concept of a style to exist as an autonomous entity there must be incremental validity in terms of accounting for variance beyond what is explained by relevant personality factors. Under these conceptual requirements, the construct of cognitive style can be described as being placed at the intersection between personality and cognition. In this capacity it may serve an important function as a *bridge concept* that may bring personality and cognition together in a concerted way to optimize performance. Indeed, this is how the concept was initially conceived over 80 years ago. An implication of this is that several cognitive styles should be more strongly related to various personality constructs than to intelligence, and that style should be seen as a disposition as well as a situational preference. Very few, if any, style studies have controlled adequately for the effects of personality in the predictions of performance on cognitive tasks.

Third, there is the issue of a distinction between *task specific* strategies versus more general, higher order strategies, sometimes called *meta-strategies* or *executive functions*. Most researchers in the field have opted for the latter option. An implication of this is that styles should be relatively more consistent across tasks and stable over time, than task-specific cognitive strategies. This issue has, however, received relatively little attention in research on cognitive styles.

Fourth, there is the issue that style theories have flourished without being part of any unifying model or framework for the several style constructs. Some progress has nevertheless been made in this regard. Elena Grigorenko and Robert J Sternberg suggested a conceptual framework where styles could be placed under the headings *Cognition Centered* approaches (including style theories that relates to cognitive abilities), *Personality Centered* Approaches (including style theories that relates to personality traits or related constructs), and *Activity Centered* Approaches (including styles that relate to learning and teaching). Richard Riding and Stephen Rayner described a theory where a large number of cognitive style constructs are organized under two superordinate style dimensions called Verbalizer–Visualizer and *Analyst–Wholist* styles. The first of these describes typical modes of mental representations and the second pertains to the way in which the individual organizes information.

Beyond this, Li-fang Zhang and colleagues have suggested that style theories can be classified as *Type 1* (preference for unstructured tasks, norm breaking and original thought), *Type 2* (preference for structured tasks, conformity, respect for rules and authority), and *Type 3* (situation specific adaptability of Type 1 and Type 2 styles). Finally, Maria Kozhevnikov has argued that most style constructs could fit into a model with two dimensions: *superordinate* dimension was seen as related to executive cognitive functioning (associated with flexibility in the choice of lower level strategies), and (at least) two *subordinate dimensions* seen as describing either low-level information processing (like perception) or more complex cognitive activities (like decision making). However, currently no agreed upon general typology of cognitive styles yet exists.

Fifth, there is the question of whether style should be defined as being unipolar or bi-polar. In the former case, the two ends of a style continuum should be associated with opposite characteristics. People located in between the extreme scorers are seen as being more flexible or mixed in their dispositions. Bipolarity can be inferred to the extent that there is a relatively strong and negative correlation between the two polar opposites. Related to this issue is also the position taken by Eugene Sadler-Smith that, for example, intuitive-analytical cognitive styles actually describe two different cognitive processes, with a versatile style combining the two. Similarly, Chris Allinson and John Hayes posited that the *Analytic–Intuitive* dimension describe two poles on a continuum. A further distinction is described as *Mobility–Fixity*, where mobile dispositions describe a tendency to use both styles, whereas fixity describe a tendency to use only one. Associated with the bipolarity issue is also the assumption that both poles of stylistic constructs should in a general sense be value free.

Sixth, there is the issue of whether cognitive style theories should operate as *self-contained* models or as derivatives of more *general theories* of cognition and eventually also linked to theories of personality or abilities in a broader perspective. The latter alternative implies that styles should be defined in ways that make their operationalizations meaningful beyond the style construct itself. This has not always been the case for style theories, and a large number of theories have been formulated based on loosely defined ideas. Still, Samuel Messick made important strides in anchoring conceptualizations of cognitive styles more firmly and suggested that styles evolve around underlying profiles of abilities, traits, or motives. Moreover, while styles can be quite substantially influenced by both ability and personality, they should also be seen as shaped by individual experiences and adaptations. Robert Sternberg formulated a theory where styles are part of his more general theory of Mental Self-Government, and where styles describe different ways of using one’s abilities. Moreover, Øyvind L. Martinsen and colleagues developed a theory where style has developed based on a profile of personality traits and where style is seen as task-specific competencies and integrated with Herbert Simon’s information processing theory and the classic theory of achievement motivation to predict performance. Along similar lines Maria Kozhevnikov suggested that cognitive styles typically describe dispositions towards using different kinds of heuristics that we use to process information about our environment.

Seventh there is the question of whether styles are *trait-like* and relatively unchangeable, or *state-like* and adaptive based on situational constraints, training, or development. Elena L. Grigorenko has speculated about whether styles are stable and share some of

the genetic influence on intelligence and personality but pointed out that genetic research on styles remains nonexistent. In a recent comprehensive review of research on intellectual styles, Li-fang Zhang argued that at least some styles can be modified, but also that there is a lack of longitudinal studies that can support this idea. The question remains open.

Despite the challenges associated with the seven issues above, cognitive style has been a popular construct in psychological and educational research. Since the early 1950s and earlier, a large number of studies on style constructs have been published in journals and in edited and authored books. A number of these have touched on the *relationship between cognitive styles and creativity*. Moreover, several theories have been postulated over the years, and cognitive style has indeed been looked upon as an interesting construct within the field of creativity. The main reason for this is that it has been seen to have the potential to supply some of the missing pieces of the puzzle from the classic experimental research on human cognition. Here individual differences generally have been perceived as irrelevant or as a 'nuisance' in terms of unexplained variance. The construct of cognitive style has been used to describe *how* individuals process information in different ways and to show that the inclusion of such individual differences adds to our knowledge of human cognition beyond the reaches of both classical experimental research and multivariate studies of intelligence or personality. As regards the relationships among cognitive styles, creative problem solving and creativity, an important issue has been to investigate whether people solve problems or create novel and useful solutions in predictively different ways.

Below, we briefly present a number of style constructs, that seem to be most closely linked to the issue of creativity.

Theories of Cognitive Styles and Their Relationship to Creativity

Field Dependence–Independence

In 1954 research was initiated on field dependence and independence as a stylistic construct. This construct was defined as a perceptual variable, representing the degree of autonomous functioning in assimilating information from the self and field. Field dependence–independence was defined as a bipolar construct. Field-independent people excel at cognitive restructuring, while field dependent people are more socially adept because they are more sensitive to external referents. Moreover, field-dependent and field-independent types could be *fixed* (those who appeared not to have any capacity for the properties associated with their opposite style), or they could be *mobile* (those who appeared to be more flexible with regard to the two types of styles). Thus, some people were seen as more flexible than others with respect to their stylistic dispositions.

These stylistic properties were measured with two different tests. One was the Rod and Frame Test, where the task involved ignoring a visual or postural context to locate a true vertical. The other was the Embedded Figures Test, where the task involved locating a previously seen simple figure in a new figure where the simple figure had been embedded within a more complex design.

Results from several studies supported the hypothesis that field-independents are more creative than field-dependents, also in studies that controls for intelligence. Previously, it was also argued that mobile Field Independents would be more creative because of their ability to move flexibly between the two stylistic modes. This has been supported by recent research.

It is nevertheless necessary to interpret these results and ideas cautiously given the present conceptual status of the theory of field dependence–independence. Serious criticism has been raised against this theory, e.g., the frequently found high correlations with measures of general mental ability and, particularly tests of spatial ability. Based on such findings the status of the concept as a genuine style construct is uncertain.

Reflectivity–Impulsivity

This cognitive style dimension relies on differences in decision speed under conditions of uncertainty. Its primary measure was the Matching Familiar Figures Test, where individual differences in speed and accuracy of decision making (conceptual tempo) under uncertainty were measured. Time to make decisions and errors in the accuracy of decisions were combined to categorize children as *impulsives* or *reflectives*, or more precisely as *fast-responding/high-error*, *fast-responding/low-error*, *slow-responding/low-error*, or *slow-responding/high-error* types.

The study of the relationship between reflectivity–impulsivity and creativity has provided mixed results. No significant differences were found among conceptual tempo groups on a series of common creativity and problem-solving tasks. It has, however, been shown that fast/accurate and slow/inaccurate subjects obtained greater originality scores than slow/accurate and fast/inaccurate subjects. Significant relationships also have been obtained between reflectivity–impulsivity and some facets of musical creativity, and reflective subjects have been shown to score higher than impulsive subjects on the Torrance Tests of Creativity. Although no clear pattern in these findings has emerged, where significant relationships have been obtained, reflectives have had higher scores.

Holist – Analytic Theories

In Richard Riding and Stephen Rayner's organization of style theories a number of style constructs have been placed in the Holist-Analytic category that bear clear relevance to creativity. Among these, the style theory advanced by Michael Kirton in 1976 has made a special contribution to the study of creativity. In this theory *Adaptors and Innovators (A-I)* are seen as describing two qualitatively different and consistent individual approaches in preferences for different ways of solving problems and approaching tasks involving creativity and in decision making. Kirton makes a distinction between *style* and *level of creativity*. Level of creativity is

measured through evaluation of the quality of people's creative ideas or products. Style of creativity is supposed to capture the different approaches of adaptive creativity directed toward improvements within an existing framework, compared with innovative approaches directed towards basic change of the existing state of affairs. However, individuals are not seen as being fixed at either end of the A-I continuum, and when individuals depart from the behavior associated with their preferred style this has been called 'coping behavior.' It is argued that differences along the adaptive-innovative continuum should be unrelated to variations in the level of creative performance.

In several studies, it has been demonstrated that the Kirton Adaptor-Innovator inventory (KAI) does not correlate with measures of intelligence. Yet there is a relatively strong relationship has been obtained between scores on several personality traits and the KAI, for example, between KAI scores and the sensation seeking trait. Other researchers have found that the A-I continuum is positively related to Extraversion and Openness, and negatively to Neuroticism and Conscientiousness in the five-factor model of personality. Yet, there seems to be a need for studies showing that the KAI adds to prediction of creativity (incremental validity) by abilities and personality.

As regards creativity, research shows that KAI scores are generally uncorrelated with measures of divergent thinking. This has been taken as support for the idea that there are different types of creativity along the adaptive-innovative dimension that are independent of level of creativity. Generally speaking, however, zero correlations as such do not support the hypothesis that there are different types of creativity. Self-reports on both style and creativity evaluations do not necessarily support this idea. Moreover, a study by Robert Dew from 2009 suggests that Adaptors may be more motivated to be creative when creativity is perceived as useful, thus suggesting that the relationship between this style dimension and creativity depends on motivational cues in the situation.

Although Kirton's theory is interesting, the bulk of research on the theory is correlational or factor analytic. This implies that some of this research may lack the necessary controls to permit making causal inferences. This is a limitation when it comes to testing the main hypothesis in the adaption-innovation theory. Further efforts should thus be made to demonstrate experimentally that A-I indeed utilize qualitatively different strategies uncontaminated by level of creativity, and that these strategies have different implications for the direction of effort in creativity, problem solving, and decision making. Kirton's idea of a distinction between the style and the level of creativity is useful, but the support for this idea is so far too limited to warrant such a conclusion. Arguments have also been presented to the effect that the distinction may be conceptually flawed. Specifically, it has been argued that the concept of innovation/innovative logically requires the concept of creativity to be involved, whereas the concept of adaptation/adaptive does not.

Another theory in the holist-analyst category of styles is the theory of *Assimilator-Explorer (A-E)* cognitive styles which has been proposed by Geir Kaufmann and later elaborated by Øyvind Martinsen and colleagues. The theory of A-E styles describes individual differences in dispositions toward using problem solving strategies. Kaufmann based his original theory on cognitive schema theory with special reference to Piaget's core concepts of assimilation and accommodation. Assimilators are seen as more rule bound in problem solving behavior, and as having a disposition toward interpreting new events in terms of existing knowledge. In an expansion of Piaget's concepts Explorers are seen as having a disposition toward novelty seeking, which manifests itself in a search for new types of solutions and new ways of solving problems without a requirement of external pressure to do so.

This stylistic distinction has been found to be uncorrelated with general intelligence while they correlate quite strongly with a motivational factor, and also with all the factors in the five-factor model of personality, in particular with Openness to experience. Significant differences have been found in mean scores for students in different types of educational settings, with art students having the highest scores (more explorative). A significant correlation also was found between the A-E styles and scores on a creative activities' checklist (Explorers having higher creativity scores), but there was only a weak, yet still significant, correlation with measures of verbal and figural fluency. Finally, it has been found that inventors with registered patents had a more explorative style than a relevant comparison group. Taken together, the correspondence between the A-E theory and the pattern of empirical findings is consistent with the requirements in basic definitions of cognitive style and shows an advantage for Explorers in creativity.

However, other studies have sought to validate core premises of the A-E theory more specifically. It has been found that Assimilators need task-relevant experience to use their preferred mode of processing efficiently on creativity tasks, while Explorers are more proficient when exploring the task environment when they have low levels of experience (which by implication means high novelty). It has also been found that Explorers and Assimilators performed differently based on instructions to utilize different types of problem-solving strategies on creative problem-solving tasks. This finding was interpreted as experimental evidence for the idea that people with different stylistic dispositions normally utilize qualitatively different problem-solving strategies where the experimental instructions may have compensated for task specific challenges associated with the poles of A-E styles.

Based on findings like these it has been argued that A-E styles can be seen as a relevant indicator of task-specific competence. However, such task-specific competence does not necessarily lead to superior performance. Other conditions contribute to impairing or facilitating performance beyond the degree of compatibility between stylistic dispositions and task demands. In this regard interactive effects between stylistic disposition, degree of task-relevant experience, cues in the situation such as solution hints, the salience of motivation arousing conditions, as well as positive mood, *together* may influence performance. This dynamic interplay may be explained by a theory of optimal motivation for the task, where task characteristics, styles, affect arousing conditions, and achievement motives together determine the quality of performance. Such complexity indicates the difficulty of research in this area. Yet, Explorers may be expected to perform better on complex and novel tasks, but this tendency declines when motivation or positive mood is in the higher range. On the other hand, Assimilators tend to perform better when tasks are complex but more structured, but this tendency goes down when motivation is in the higher range.

Based on this, it can be argued that the A-E styles has its main effects on creativity mainly in interaction with other influences. The theory has the advantage that it can be coherently integrated with theories of personality and achievement motivation, and recent theories of information processing. In such theories creative problem solving is conceptualized as search in large problem spaces, and/or as diverted search in an incorrect problem space. The perceived task structure is determined by the availability of solution constraints and adequate cognitive strategies in dealing with such constraints. It has been posited that the A-E styles describe individual differences in preferences for such heuristics. Thus, research on the A-E styles may shed new light on the relationship between motivation and creative problem solving, individual differences and expertise in problem-solving, as well as the relationship between positive mood and creative problem solving. Consequently, this theory may have fruitful implications in several areas of research extending beyond the domain of creative problem-solving.

Thinking Styles

In 1988 Robert Sternberg based his style theory on a governmental metaphor which rests on an assumption that people govern themselves in a way similar to societies. Thus, thinking styles are described as different aspects of self-government and include functions, forms, levels, scopes, and leanings. The three major *functions* are the *legislative (creative)*, *executive (implementive)*, and *judicial (evaluative)* styles. Four major *forms* of government are the *monarchic* (preference for one goal at a time), *hierarchic* (preference for multiple goals ordered in a hierarchy), *oligarchic* (preference for multiple goals, where each is equally important), and *anarchic* (avoids rules and systems). Two basic *levels* of government are the *global* (preference for general problems demanding abstract thought) and the *local* (preference for tasks that require detail and precision). Two domains in the *scope* of government are the *internal* (preference for tasks that allows people to work alone) and the *external* (preference for tasks that allow working together with others). Two core *leanings* are the *conservative* (preference for the familiar and traditional) and the *liberal* (preference for going beyond existing rules and regulations).

Sternberg's theory shares basic similarities with other theories of cognitive styles: styles are placed at the interface between personality and cognition, express the manner of cognition, and should be uncorrelated with intellectual capacity. However, thinking styles can still be related to more local domains of capacities.

Sternberg's theory, like Kaufmann's, has been developed within a theory of intellectual functioning, which may simplify both the operationalization and the evaluation of the stylistic dispositions compared with other style theories. Still, cognitive styles have typically been defined as bipolar constructs, while thinking styles are defined as unipolar constructs that together create a stylistic profile. The bipolarity assumption that is common in most theories of cognitive styles is thus rejected in the theory of thinking styles, although this may be an empirical question.

Sternberg included styles in his theory of creativity and found negative relationships between creativity and the executive, conservative, and monarchic styles. A combined score on these styles was significantly and negatively correlated with an overall measure of creativity. Contrary to theoretical expectations, the legislative style was not correlated with the measures of creativity. However, other studies have shown that giftedness was associated with Type 1 style and that creative writers also scored higher on the same type of style. Also, recent studies have emphasized that Type 1 style is the better predictor of creativity, including creativity-promoting teacher behavior. Taken together, a growing number of studies have strengthened the validity of the theory of thinking styles and its relation to creativity.

In more recent conceptualizations of the theory, three superordinate dimensions of styles have been described, with different aspects of thinking styles included within each. The first of these, labeled '*Type 1 style*,' includes the legislative, judicial, global, and hierarchical facets. The second, labeled '*Type 2 style*,' includes the executive, local, monarchic, and conservative facets. The third style, labeled '*Type 3 style*,' includes the oligarchic, anarchic, internal, and external facets. A number of studies have shown that the Type 1 style is associated with openness to experience and conscientiousness in the five-factor model of personality, higher adaptiveness, higher self-esteem, enhancement of positive emotions, the motive to approach success, better mental health, and more. Type 2 style has been associated with neuroticism, the motive to avoid failure, and other typically conceived, negative influences, while tendencies to have higher academic achievements were also evident in association with this style. Further studies have focused on educational issues. The theory has moved away from a position where all styles have equal value. Zhang suggest that the three types of styles may serve as an organizing framework for style theories in general.

Alternative Theories

Some of the more recent theories of styles have, in various ways, been related to the process of creative problem solving. One such theory has been developed by Min Basadur. This theory maintains that there are two main stylistic dimensions, one describing two different ways of *acquiring* knowledge, and the other relating to two different ways of *using* knowledge. The two different ways of getting knowledge are through experiencing and ideation, and the two different ways of using knowledge are through thinking and evaluation. Various combinations of these stylistic attributes yield different typological interpretations, and these are labeled *Generator*, *Conceptualizer*, *Optimizer*, and *Implementor*. This measure seems to be based on a measurement technique that has some limitations while the constructs themselves seem to echo the idea of problem finding versus problem solving, which is also related to creative producing and creative solving of problems and ideas. Recent research has sought to improve the instrument as regards reliability and other measurement qualities.

A second theory in this category has its roots in the brainstorming-oriented theory developed by Alex Osborn and Sydney Parnes and is promoted by Gerard J. Puccio who maintained that there are four different individual preferences related to the process of creative problem solving. These four preferences were labeled *Clarifier*, *Ideator*, *Developer*, and *Implementer*. The Clarifier preference describes aspects of data finding and problem finding in the Creative Problem-Solving framework. The Ideator preference describes aspects of mess finding and idea finding. The Developer preference describes aspects of solution finding and the planning aspects of acceptance finding. The Implementer preference describes action-oriented aspects of acceptance finding. The theory and its measure have been developed in stages, and currently factor analyses and correlational analyses with other popular and creativity relevant measures have been undertaken. Correlations with the Adaptor-Innovator dimension and the five-factor model of personality have been identified. However, it awaits further and more rigorous analysis.

A third theory has been called VIEW and assesses creative problem solving style. It has been developed by Edwin C. Selby, Donald J. Treffinger, Scott G. Isaksen, Kenneth J. Lauer, and others as a novel integration of constructs, while it also seems to be operationalized in a way that is close to some existing style and type constructs. Its main focus is individual differences in relevant aspects of creative problem solving, and it measures three styles. The first style is labeled *Orientation to Change* and describes a distinction between *Explorers* and *Developers*. The second style is labeled *Manner of Processing* and describes a distinction between *External* and *Internal* ways of processing. Finally, the third style is labeled *Ways of Deciding* and describes a distinction between a *People* and a *Task* orientation. The items in this inventory represent what may be conceived of as semantic differentials which may represent preferences between true opposites or contrasted constructs. Factor analyses has supported the conceptual three factor distinction in some studies, but not all, and a number of correlations with type, trait, and other style measures support the theory's validity. Lack of correlations between this measure and measures of creative abilities have been taken to support a distinction between style and level of creative ability. Other studies support other aspects of construct validity, and results from a recent quasi-experimental study indicates that style-based training and coaching over a nine-week interval may increase participants' creativity. Some design limitations may still caution against this interpretation.

A fourth theory has had the aim to integrate creativity relevant constructs from previous style-, motivation- and trait-research on creativity. In this approach Øyvind L. Martinsen developed the Creative Person Profile (CPP) which included 7 broad factors that were based on 27 more specific, creativity relevant constructs. Among these, *Associative orientation* (fantasy, absorption, playfulness etc) and *Flexibility* (adaptability, restructuring etc) were seen as cognitively oriented constructs aimed at ideation, fantasy, and restructuring. *Ambition* (need for power, need for recognition, need for attention etc), *Motivation* (need for achievement, autonomy, novelty seeking etc), *Need for originality* (preference for rules (R), opposition against conventions, rigidity (R) etc) were motivational and attitudinal. *Agreeableness* (Concern for others, Friendliness and Critical attitude) were seen as interpersonal but also as describing problem finding through being critical and less concerned with interpersonal considerations. *Emotional instability* (mood swings, neuroticism, low confidence etc) described tendencies towards negative emotionality. Five of these constructs overlapped with the five-factor model of personality, while all seven factors were at best weakly related to intelligence. Among the seven dimensions some were found to be associated with performance on creativity measures like ideational fluency, creative problem-solving tasks and a remote associate test, and also with accomplishments in diverse creative activities. Other constructs were related to differences between groups like artists, who are generally held to be creative on the factors, and a group with other types of backgrounds. However, few studies have been done based on this theory hitherto.

Discussion and Future Directions

There are important limitations of the research in this area. The *first* concerns the validity of cognitive style constructs, the *second* concerns the design of studies on cognitive styles and creativity, and the *third* concerns the perspectives on style-creativity research.

First, further research is still necessary to settle more definitively whether several cognitive style constructs represent *autonomous* constructs, or whether they eventually boil down to a mix of stylistic expressions of ability and personality constructs. Several style constructs stand in need of sharper examination on the merits of their *incremental validity* against ability and personality factors. That is, does one advance or handicap the field by mixing personality and ability/preference and power/concepts into style? The jury is still out on this issue.

One interesting path for future style research can be inspired by research on compound traits, or emergent traits, which has a long history in research on personality. Such traits, like integrity, emotional intelligence, managerial potential and more, are typically measured by criterion referenced tests that purport to measure specific behaviors in applied settings. Common for several such traits is that they are factorially complex and typically related to Neuroticism, Agreeableness, and Conscientiousness. Thus, styles may be seen as describing specific, cognitive phenomena that mediate profiles of personality traits and/or abilities. Consequently, to the extent that style theories can be placed in a conceptual space with personality and ability constructs and shown to have some kind of legitimacy beyond the traits that they originate from, it would further validate style as a useful construct in psychology. A clarification of such ideas would also explain further the factorial complexity typically observed for some style measures and the multiple personality correlates for the same measures. In this regard, styles could be classified as Intellectually focused Personality Scales (IPS) with similar potential and limitations as the compound traits previously mentioned, or Criterion focused Occupational Scales (COPS). These ideas have been elaborated by Adrian Furnham and others.

Second, the research designs most frequently applied in stylistic research on creativity still seem to be non-experimental. This limits our understanding of the results and the possibilities of making causal inferences about style-creativity relationships. If

we are to investigate the possibility that cognitive styles, for example, describe different ways of being creative, it is indeed necessary to apply aptitude–treatment interaction studies to shed light on such issues. In research designs like these, individual differences in cognitive styles are combined with experimental manipulations of task contents, work conditions, or other situation conditions, with the inclusion of necessary controls for alternative interpretations in terms of abilities and personality factors. Unfortunately, such more powerful research designs have been scarce during the history of style research.

Third, it seems necessary to investigate further the relationship between cognitive styles and creativity based on different conceptions and measures of creativity. Presently we have at least four different perspectives on creativity that are important for stylistic research. The *first* one of these perspectives is a micro or ipsative perspective, where an individual's creativity is based on a comparison between the degree of novelty in a product or idea and that in the same person's previous products or ideas. This is an individual perspective where everyone can be seen as creative only in the sense of increasing their creativity. A *second* perspective is a macro or normative perspective, where a person's creativity is compared with other persons' creativity from an objective perspective. This is the invention or innovation perspective, where only a few people are creative – this is the idea of the normal distribution. The *third* perspective is a component perspective, which can be integrated with either of the two preceding micro and macro perspectives. Here, the stylistic influence on various subcomponents of creativity (like insight, analogical reasoning, remote associations, ideational productivity, convergent thinking, etc.) can be studied. The *fourth* and final perspective is the domain specificity of creativity; i.e., if some styles predict creativity in certain domains but not in others? Style researchers need to be more aware of the several conceptual and operational distinctions that can be made in creativity research, and to adjust their research designs accordingly. Thus, the criteria and designs in style–creativity research must be specified based on *a priori* theoretical and/or operational definitions of creativity or creativity relevant processes.

Based on this overview of current research on individual differences in cognitive styles, the hypothesis that cognitive styles do indeed have a function in creativity seems reasonable. Still, the present theories need to be developed further in order to yield more precise information on the relations between style and creativity. Meeting this requirement also depends on further progress in creativity research where the criterion problem is multifaceted and difficult to solve.

The evidence is not clear enough for a reviewer of the relationship between the style and creativity literature to despair or rejoice. The pessimist would point to the endless models, measures and theories of cognitive/learning/thinking styles, none with very impressive evidence of psychometric validity, particularly convergent, divergent, construct, and predictive validity. They would also point to the creativity literature which remains for differential psychologists something of a backwater, with little real development in terms of measurement. In other words, this is the relationship between two conceptually unclear and methodologically weak fields. The optimist on the other hand, may point to a lively applied and cross-disciplinary rather than moribund field using more sophisticated methods of research to investigate the intriguing issue of creativity. Both are very big areas and it may be that the field will best advance by concentrating on a highly specific area. Thus, if we have problem finding versus problem solving and arts versus science (divergent vs. convergent) problems, it is possible we could find the cognitive style associated with divergent problem-finding more convincingly. The importance of this level of analysis has been recognized.

To collaborate is to work jointly with one or more to the same end. There are multiple examples of famous creative collaborators in popular culture across various domains from music (e.g., Paul McCartney and John Lennon), art (e.g., Frida Kahlo and Diego Rivera), scientific innovation (e.g., Marie and Pierre Curie), opera (e.g., Gilbert and Sullivan) or even magic (e.g., Penn and Teller). Creative collaboration also occurs in groups from large scale movements such as the Romantics or Pre-Raphaelites who collaborated across different artistic domains to smaller groups such as members of a jazz ensemble or improvisational theater troupe. In all cases, group members are commonly accepted to have intimate involvement in the emergent creative works and oftentimes, the creativity is necessarily dependent on the involvement of others (Sawyer, 2004). These collaborations are often seen as tempestuous but are also productive and arise from a close intimacy maintained over an extended period of time.

This entry starts by assessing the differences between group creativity and collaboration. We then move to make a distinction between direct collaboration, which is clear and explicit, and more indirect forms of collaboration where the collaborative traces of other unnamed partners (whether human or not) can still be clearly observed. Finally, there is a look at the challenges ahead for those who research this unique and complex phenomenon and also the implications of adopting a collaborative perspective on creativity as a whole.

The Importance of a Collaborative Perspective on Creativity

Current research on creativity shows a tendency to focus on the attributes of the creative individual or casts the individual's internal thought processes as the causal factors that produce creative cognition. That this viewpoint is more prevalent in creative cognition research than creativity research in management which is more applied and has more of a focus on team cognition indicates its limited scope. This research focus necessarily privileges both the individual as a unit of analysis and a methodology which casts creativity as an additive and generally linear process. Such an epistemological position pins the locus of creativity on the individual and casts group creativity as something that occurs when a measurable outcome is formed by the interaction of these individual creative units (Glăveanu, 2011).

However, such a research program, while elucidating some aspects of the creative process, does not reflect collaboration as documented across other naturally occurring domains. Those who study collaborative creativity as distinct from group creativity assert that some creative processes and products cannot be fully understood at the individual level of analysis and that group level analysis is necessary (Glăveanu, 2011; Sawyer, 2004). This is true whether those groups are defined formally and recognized as a contained ensemble of participants (e.g., a football team) or less formally as a fluid ensemble of direct and indirect collaborators. Research into collaborative creativity approaches creativity as an in-between process with a final creative product that emerges from the combination and interaction of different, human (and even non-human) participants yielding a complex process which cannot be reduced to individual units of analysis.

The Distinction Between Group Creativity and Collaboration

There is not a consistent distinction between group and collaborative creativity in the research literature and although different researchers have pushed to make it clearer, the two terms are often used interchangeably. Traditional laboratory studies investigating how people create together (e.g., research on brainstorming; [Oxley et al., 1996](#)) have come to the often-surprising conclusion that working in groups reduces creative output whether that is assessed as the number of creative thoughts or the quality of those thoughts.

However, it is not clear that the conclusions of assessments of group creativity reflect creative collaboration and certainly not collaboration as it more commonly found outside of an experimental setting ([Montuori and Purser, 1997](#)). Such naturally arising and often self-selecting collaborations are qualitatively different to experiments of group creativity conducted in a lab. Lab based studies assess how a creative product, which could potentially be produced by an individual, changes when produced by more than one person. This position assumes that the other people in the process are simply another input into the input—process—output schema of individual cognition.

As such, this research focuses on such things as process gains and losses when assessing group performance against the benchmark of individual performance reflecting a belief that there is a measurable outcome which could be achieved by an individual as much as by a group. A process gain is when a group working together outperforms the expected performance of someone working alone, a loss the inverse. Often, actual groups are pitted against nominal groups to create this benchmark. A nominal group in this instance is typically made up of the scores of matched individuals who have experienced the same task alone and whose scores are artificially tallied to produce a 'group' score. This artificial situation does not reflect collaborative creativity as understood in the wider literature.

The focus of this entry will be on collaboration that involves a creative product that could not be produced by a single individual and, in this context, relative process losses and gains become less important. [Moran and John-Steiner \(2004, p. 11\)](#) referred to collaboration as “an intricate blending of skills, temperaments, efforts and sometimes personalities to realize a shared vision of something new and useful.” Regarding collaboration as a naturally occurring relationship between two or more people often leads to changes in methodology with a focus on a qualitative, idiographic approach exploring how non-substitutable components interact. These components will almost certainly have different qualities to each other and thus products of collaboration as a complex system are best considered as truly emergent—that is irreducible to their constituent parts ([Sawyer, 2004](#)). In order to capture such creative phenomenon, it behooves us to extend the level of analysis beyond individual processes in a group environment to group processes.

Methodological Implications

As in all areas of psychology, the epistemological stance taken on the nature of collaboration in creativity drives the methodology used to understand it. Traditional quantitative outcome measures that aggregate means across people are ill equipped to capture the unique nature of collaboration as theorized above so researchers who study complex creative systems such as a jazz ensemble often employ idiographic and qualitative method to disentangle the contingent dynamics of collaborations. The more common methods used are:

1. **Video data.** Video data can be used in both natural settings ([Sawyer, 2004](#); [Seddon, 2004](#)) and more artificial lab-based settings ([Bjorndhal et al., 2015](#)). These rich data sets allow the detailed analysis of actions, discourse and interaction with the surrounding environment. While at times traditional creativity tasks are used, the use of video data allows for a more detailed analysis of the process in real life tasks and an easier identification of communicative exchanges.
2. **Interviews.** Alongside traditional interviews, John-Steiner introduced the collaboration Q sort which invited collaborators to discuss where to place 50 statements on collaboration and then showed the resultant array to their collaborator (John-Steiner, 2006). The discussion of differences and similarities is meant to spark a retrospective account of the collaboration and foster reflexivity.
3. **Biographies.** Much work on eminent creative minds has proceeded from letters, diaries and biographical details of the individual and work on creative dyads is no different when it comes to using this rich biographical detail to make inferences about the creative processes involved when two or more people work together.
4. **Conversation Analysis.** Alongside video analysis, a detailed look at how collaborators synchronize their utterances can be a good measure of integration and alignment in the creative process. This kind of analysis reveals both the content of communication and, more importantly, communicative patterns among collaborators.

Direct Collaboration

In many cases, collaborations are clearly defined and acknowledged cases of creative partnerships consisting of more than one named contributor to a final creative work. We characterize these as direct collaborations where collaboration is seen as two or

more people intentionally working toward the same goal. These collaborations are formed from intentional partnerships arising from an intimate relationship built up over time.

Measuring Collaboration in the Lab

It is not impossible to measure true collaboration in the lab, but it requires a different approach and the understanding that working together does not necessarily indicate working *collaboratively*. In a series of papers, Johanne Philipsen explored how people working in groups produced and developed new ideas as they worked with LEGO bricks. She video recorded teams of 3–4 participants as they built LEGO models of concepts such as “justice” and “collaboration”. Clearly, such concepts don’t directly correspond to a particular configuration of LEGO blocks and accessories, hence the exercise results in contingently singular constructions determined by group dynamics. Philipsen and her collaborators used this video corpus to mine for interaction styles—inclusive, instructional, integrative—among team members and their resulting material traces, as revealed by the LEGO models produced (Bjorndhal et al., 2015).

The inclusive style of interaction is characterized by positive feedback and praise: everyone’s idea is validated and results in an uncritical quilt-like medley of ideas, “a concatenation of individual ideas” as the authors put it. The ownership of the resulting model was distributed although the final model didn’t quite work. Participants appeared more focused on smoothing interactions with strangers and ideas were not critically elaborated. The lack of familiarity among members of the team appears to be a key factor since the authors reported that this form of interaction was more likely to occur early in the test session.

The second style of interaction, the instructional style, resulted in conceptual ownership that was less distributed since one member of the team guided the construction of the model. The leader or instructor elaborated her ideas, a process validated but not challenged by other team members. As a result, the final model was more coherent, reflecting the creative arc governed by a single constructor but the group potential was not leveraged to its full extent.

Finally, in groups with an integrative style of interaction, ideas were challenged and elaborated continuously through interruptions, amplifications, and negative feedback. Ideas were not unconditionally validated but rather connected and synthesized through a distribution of cognitive labor. The material trace of an integrative style, that is the final LEGO model, was more coherent and reflected a more distributed creative process. In the instance described in the paper, the model embodied complex ideas such as the dynamics and outcomes of the presence or absence of “collaboration”. The integrative style was more likely to occur later in the problem-solving session when team members were more familiar with each other.

Close Collaborative Pairs

The integral role of familiarity when eliciting true collaboration in laboratory experiments is amplified in ‘real world’ collaborations. In these, a singular creative product is generated alongside an ongoing social relationship. These close intimate relationships—be they familial, marital, or based in friendship—can lay fertile foundations for creativity in the arts and science. The long and shared history of interests, conversations, and joint experiences forges the trust required to think freely but also to accept and seek a partner’s criticisms and alternatives; these elements can structure a productive and creative working relationship.

Innovative and celebrated sibling filmmakers include Auguste and Louis Lumière, Ethan and Joel Cohen, and Lana and Lilly Wachowski. The Wachowskis make multi layered, multi part, science fiction movies that challenge the orthodox movie narrative and which, in turn, require multiple viewings to appreciate their depth, texture and detail. They tackle issues of reality and identity, change and revolutions and the grotesque dystopian projection of corporate dominance over people and culture. The Wachowskis’ creative collaboration extend beyond writing and directing, resulting in innovative techniques of cinematography (including the bullet time method to spectacular effects in *The Matrix*) and editing (in *Speed Racer*).

Hemon (2012) described how the Wachowskis adapted David Mitchell’s (2004) “unfilmable” novel *Cloud Atlas*, the movie Lana Wachowski says she’s most proud of (Keegan, 2018). Mitchell’s novel involves a large cast of characters in six different stories spanning five centuries. Hemon (2012) depicted how the Wachowskis along with their close collaborator, Tom Tykwer, rented a beach house in Costa Rica where over weeks they segmented the novel into hundreds of scenes, sketched on colored cards, with colors corresponding to characters and time periods. These external representations were then physically manipulated, moved and re-arranged throughout a working day to determine which narrative arc worked best. This process was repeated the next day. It is through this form of distributed cognition—across three collaborators, across objects and their spatial arrangements, across time—that the film’s innovative narrative structure emerged as well as the idea of using the same cast of actors, embodying different characters, across the centuries, capturing the novel’s central idea, namely eternal recurrence.

Such an intimate collaborative relationship produces creative pieces that are irreducible to the internal cognitive processes of the individuals. Rather, they can only be understood as arising from a unique and contingent collaborative process. Moreover, in the case of long-term artistic collaborations like the Wachowskis’, such works can only be understood when situated in a timeline in which the creative and personal are not only indistinguishable, but their very entanglement is an essential element of that creativity.

Artistic Collaboration in Groups

Some forms of artistic creativity are explicitly collaborative and necessarily relational; these cannot be carried out by a single individual, however talented. Group jazz improvisation is one such art form which simply cannot be understood in terms of individual,

conscious cognitive processes. This form of group creativity is so explicitly collaborative that Seddon (2004) suggested it generates an “empathetic creativity”, that is, a creativity that is ontologically dependent on the presence of others. Indeed, such groups are a fundamental challenge to a reductionist notion of creativity, not only because an analysis of the individual’s creative output would not capture the final product in a satisfactory manner, but also because it is impossible for the individuals in the group to know, let alone shape the creative process. In improvisational performance the social group is not only conceived of as an abstract influence, but it is present at each moment of the creative act and the resultant piece is explicitly interactional. When assessing the creativity of such a group, one can’t just look at the product because it is necessarily ephemeral, so the listener must take into account the process, and the practice of music making; the “creative process and the resulting product are co-occurring” (Sawyer, 1992, p. 253).

Furthermore, band members cannot be simply exchanged for other equally talented members because music making in such ensembles is a dynamic and shifting mix of formal and informal approaches. As is the case with the types of close creative collaborations outlined above, creative processes in this environment are informed by social processes as much as the act of creativity itself (Kenny, 2014). Importantly, satisfactory improvisation in such groups does not happen spontaneously but rather arises from social interactions that act as backdrop to supply the level of trust necessary to work collaboratively (Kenny, 2014; Seddon, 2004). The creativity is enacted in the moment, but the collaborative ties are formed over time. In her ethnographic study of creative collaboration in a jazz ensemble, Kenny wrote of a “sense of camaraderie” (p. 4) and a “shared history” (p. 5) and Seddon told of two members of the band he studied who had attained a higher level of “sympathetic attunement” (p. 73) through spending time playing and traveling together. The piece of music then emerges from this mix of current work and shared history and cannot be understood simply as the addition of talents from interchangeable components in an easily generalizable model.

It is clear that a full understanding of at least some domains of artistic creativity requires understanding the complex dynamics of collaboration between people because the collective nature of the performers is an essential part of the creative process and product. In improvisational performance art, these dynamics are particularly important because the ephemeral nature of the product places the emphasis on the process and, in fact, collapses the distinction between the two.

Collaboration in Scientific Creativity

Scientific creativity is more commonly thought of as innovation, but it requires a level of creativity that is similar to the arts—the creation of something novel and valuable. Indeed, the parameters of novelty and value may be rather easier to establish in scientific creativity. Scientific collaboration is not a new phenomenon—the first co-authored paper appeared in 1665. There has, however, been a significant increase in scientific collaborations with ambitious projects such as the Large Hadron Collider pooling resources in order to further scientific discovery and creativity in way that a single team cannot afford to do. Co-authorship of scientific papers has been rising steadily both in terms of the numbers of authors and the number of countries from which those authors are drawn. This rise in collaboration is shaped by the increased ease of international communication alongside the need to share more advanced and expensive technological resources.

Increased collaboration has a positive impact on productivity and the citation level of individual researchers, but it also has a wider impact; it effectively increases the range of what is possible in scientific research. Beyond the pooling of financial resources, scientific collaboration allows creativity to develop in a non-linear, iterative and reciprocal manner. The benefits of scientific collaboration are not just realized by a brute force increase in numbers but also by encouraging and exploiting disciplinary diversity. As seen above, what emerges is more than a linear, additive formula treating collaborators as interchangeable units. This transdisciplinarity is essential to capitalize on serendipitous discoveries.

As collaboration occurs across disciplines, it encourages diverse groups of researchers to pool different areas of expertise to create something that would not be possible for one individual. This, in turn, allows individuals to become increasingly specialized within a team of other specialized individuals which they would not be able to do without offloading some skills to others. This creates an iterative relationship between the individual and the group extending beyond an analysis of the scientist as an individual. Moreover, such relationships are marked by a similar level of trust as the more standard artistic collaborations. The complexity of modern scientific collaboration supports a specialist rather than a polymath so it requires relinquishing individual control and therefore cannot be analyzed at a purely individual level.

Indirect Collaboration

Beyond the direct and documented collaborations outlined above, there is a growing research field which extends the understanding of collaboration to encompass objects, people and ideas which do not collaborate in a formal way, but which nonetheless shape and are agentic in the final creative process or product.

Cultural Collaboration: Sociocultural Serendipity

Not all collaboration is planned, direct and documented; some collaborations remain undocumented or even unnoticed but leave clear traces on creative output that is indistinguishable from the more direct collaboration outlined before. The phenomenon of multiple discovery when a scientific invention occurs simultaneously in different parts of the world, cannot be explained without reference to the social nature of creativity (Simonton, 2019). Beyond these moments of unrelated, simultaneous

innovations, certain “golden ages”, elucidated by historiometric analysis, support an essential role for the socio-cultural milieu. These particularly fertile moments in the history of innovation and creativity suggest that indirect collaboration is essential to the rise of eminent creative geniuses. Renaissance Florence is one such time period for artistic creativity as is the golden age of scientific creativity in the Islamic civilization (Simonton, 2019). These golden ages, with a concentration of eminent creative individuals, underscore the importance of non-intentional, spontaneous collaboration which may often be unacknowledged even by those involved.

Even those people characterized in the collective imagination as an individual genius who transcends those around them are perhaps best understood as arising from a complex network of indirect collaborations and socio-cultural forces. Take, for example, the work of Shakespeare: The modern desire to attribute authorship to one sole individual and grant him ownership of the text is anachronistic when applied to his plays which were generated when ideas of text ownership were not understood as they are today. It is notable that the entire field of authorship studies has now arisen to disentangle the phraseology and words that can be attributed to different single authors from this period. Thus, collaborations are woven into the very fabric of the texts society has inherited and these texts reflect speech patterns and thoughts that cannot be easily attributed to any one person. For example, Marlowe’s and Shakespeare’s influence on each other until the former’s dramatic death was substantive to the extent that there are still many who are convinced that Marlowe is a better candidate for authorship of the plays commonly attributed to Shakespeare.

An analysis of the role of collaboration in creativity is incomplete without taking into account that the creative process happens in a particular sociocultural field which structures, constrains and extends possibilities beyond the potential of conscious and intentional collaborations explored in the previous section. There are fertile moments in history that generate cultural moments from which new creative products emerge. We would term this sociocultural serendipity. Serendipity describes a process beyond chance, characterizing moments in which both luck and the individual are necessary but not sufficient in themselves. Rather, serendipity is a relational term and generates a framework to understand how creativity can be reliant on both the exceptional talents of an individual and the unique characteristics of a certain time period without privileging either. This sociocultural serendipity reflects a non-intentional but nonetheless vital collaboration between the individual and the sociocultural background.

The Audience

The role of the audience is pivotal to all creativity. Performance art is particularly heavily and necessarily reliant on audience participation; anything which occurs in the absence of an audience is not considered a creative act, it is a rehearsal. In compositional performance art, the final creative product is nominally created by the playwright, performer or choreographer but interpreted by the actors and, crucially, the audience. To return to the example of the jazz musicians, the interaction with the audience is typically considered a key element of the interactional context (Sawyer, 1992). Furthermore, in some cases, the audience is an active participant in the piece of art as it unfolds, even if not at the compositional stage.

Take, for example, Maria Abramović’s 2010 MOMA piece of performance art “The artist is present.” In this piece of work, Abramović was seated silently at a table while members of the public came to sit opposite her. While explicitly centered on Abramović and her presence, this performance was also necessarily interactional—the art and the audience became one. Indeed, one of the many creative outcomes of the piece was represented by the emotions provoked in the audience. The creative product shifted with each new visitor and generated an ephemeral process much like the improvisational jazz outlined above. While the initial creative idea arose in the artist (albeit not a socially isolated artist), the process of enacting that idea was necessarily collaborative and interactive. More recently, *Black Mirror*, Netflix’s television serial released an episode (*Bandersnatch*, David Slade [Director], Charlie Brooker [writer]) in which the audience can be actively involved and choose their own ending. Thus, while the writers and actors created the episode, the final form is a unique collaboration of their creativity and the choices of the audience. Indeed, with digital technologies making it easier to invite audience participation, this sort of asynchronous collaboration may be more common in the near future.

The same is true of art forms in which the audience is more commonly considered passive, such as the novel. For a fictional novel to function as a creative form, the readers are required to engage their imagination and to recreate the fictional world of the author. An unread book remains inert until it is recreated in the mind of the reader in the same way as a play is in a constant state of rehearsal until the moment it is staged in front of an audience. The reader has an essential role to play by taking the fiction beyond the control of the writer. This is clearly demonstrated by the intense disappointment some readers feel when there is a mismatch between a cinematic representation of characters and the character that exists in their imagination. The result emerges from the filling in of the spaces left by the writer and so is contingent on collaboration with the reader.

Material Collaboration

The creative product is often constrained by the things around it across all domains. It is a commonly reported phenomenon that the materials used in artistic creativity influence the creative act and shape and constrain what can be done.

Take, for example, the experience of working with clay. Paul March’s (2019) writings on this process reveal how the actual physical materials with which he works shapes the creative process with the delicate nature of porcelain contrasting with the more robust nature of stoneware:

The physicality of sculptural experience can be felt by comparing two different clays: stoneware and porcelain. Metaphorically speaking, stoneware is dynamic, generous and forgiving—confident in its plastic potential. Porcelain is intransigent and full of inertia. With porcelain, the act of creation and the outcome of the engagement with my hands take place within boundaries set by the clay's limited elasticity and excessive friability. Sculpting with porcelain is a tense negotiation (March, 2019, p.137).

The subtly different affordances of the material used constrain and shape the final artistic work with a similar level of influence to a human collaborator: that is, they are a causal factor in some aspects. Moreover, there is a relationship of trust and tension which mimics the intensity of the human/human relationships described above. Other artists discuss being aware of how material reacts and how they respond to a question posed by the material rather than imposing their imagination on that object (Botella et al., 2013). Creativity implies production, co-creation. Just as performance art is contingent on the collaboration with the human audience for its very existence, artistic creativity is equally contingent on materials.

Conclusions

Our understanding of collaboration in creativity takes us away from laboratory analyses of creative cognition happening in groups but being analyzed at the individual level, using measures and methodologies more suited for individual creativity. The focus on collaboration proposed here is not without its own challenges. To begin with, it is intrinsically difficult to study dynamic, developmental phenomena such as unfolding conversations and the trajectory of ideas in spaces of co-creation than measure personal traits or properties of objects. Second, the emergent nature of collaborative encounters makes it almost impossible to predict beforehand what will be produced and how. Finally, the creativity of collaborative pairs and groups is expressed at multiple levels, from the concrete outcomes they generate to the social consequences they usually have (e.g., creating group identities, fostering efficacy at a group level, promoting prosocial mindsets).

In the end, there is a tendency to reduce creativity (as is the case with many psychological phenomena) to the intentional acts of an individual which are then traced back to her internal processes, personal history or character traits. However, as argued here, creativity itself simply can't be explained fully using this level of analysis because creative processes emerge from the collaboration, explicit or implicit, of both intentional and unintentional creative agents. Even the most seemingly individual acts of creativity build on objects created through division of labor in society and ideas co-created with others, including cultural tools that are the outcomes of entire societies across time; creativity is temporally as well as socially situated. Collaborations often follow unique trajectories and their creative products emerge from the dynamic interplay of various factors that can only be interpreted in systemic and interactive terms.

Introduction

For much of history, and certainly since the time of Plato and Aristotle, creativity has been characterised as a *special talent*. A common explanation, at least until the Renaissance (which began in around 1300), was that *creation* is the sole concern of higher powers. Under this premise, creative humans must therefore be acting under the direction of those powers. Plato spoke of a creative *divine frenzy*, while Aristotle referred to a *tincture of madness* colouring the creative individual. According to this view, creative people behave the way they do because they are compelled to carry out the wishes of the gods, whether they want to or not: it has been suggested that this view is possibly pre-historic, and may have prevailed even at the time of the cave artists.

The divine-inspiration explanation of the origins of creativity persisted through the Renaissance, although with an important change: the source of creativity was thought to lie *within* individual creators in the form of a special “genius” which they possess but others do not. According to Kant (1914 [1790]), this genius is an “*innate mental predisposition*” (p. 188, emphasis added): A few people possess it as a gift from nature, but most do not. Creativity therefore remained linked with the idea of *otherness*, or even madness.

Even in modern times, creativity has struggled to break this association with exclusivity. Many of the myths and misconceptions of creativity (see, for example, Cropley and Patston, 2019) are anchored in notions that creativity is only found in the arts, or that creativity cannot be taught (precisely because it is a special talent). Many people still, as Kawenski (1991) noted, believe that creativity involves simply sitting around and “waiting for the muse to strike them” (p. 263).

Fortunately, for creativity, this view seems to be shifting rapidly in the wider population. This shift began, of course, with Guilford's (1950) modern characterisation of creativity as a vital component of human intellectual ability, and has been reinforced, for example, by studies of *malevolent* creativity which serve to break a parallel association between creativity and *goodness*.

However, it is perhaps the very recent discussions of 21st century skills, and the *future of work*, driven by the rapid onset of the Fourth Industrial Revolution, that are leading to discussions of creativity as something more than just a special talent, or a gift from the gods. Creativity, in this 21st century setting, has become something – a *skill* – that is useful and valuable. For example, the World Economic Forum's *Future of Jobs Report* (Leopold et al., 2018) emphasises the importance of creativity as a means to increasing innovation and ideation in the future of work. Creativity is a form of *human capital* – an economically valuable asset possessed by individuals – that can be developed, nurtured and exploited (see Walberg and Stariha, 1992, for a discussion). Sternberg and Lubart (1991) expressed this notion in their ‘investment theory’ of creativity, whereby individuals buy low and sell high; that is, they pursue innovative ideas that are currently undervalued, and then sell them before other individuals come up with the same idea.

As *routine*, and convergent, human activities are increasingly performed by machines and artificial intelligence, the ability to find new and effective solutions to problems – creativity, in other words – has become, as Bruner (1962) forecast, the *last bastion of human mental sovereignty*. Has creativity become, in effect, a *commodity*?

The History of Commodities

A commodity is a *homogenous economic good* – a raw material – that is of use and has value. Traditional commodities include, for example, grain, beef, electricity, oil, and precious metals. The idea of commodities existed even in the world's oldest civilisation; in Sumer (modern day Iraq), during the period 4500–4000 BCE, clay tokens or seashells were exchanged for goats or pigs. It was during the 1500s, in the Common Era, that the concept of a *Stock Exchange* was initiated by the Dutch, replacing earlier, and more rudimentary commodity trading *marketplaces*. Commodities trading was not limited to Western civilisations; there are records of rice trading in Japan in the 1700s.

The Chicago Board of Trade was created in 1848, with the primary commodities traded being corn, wheat, cattle, and pigs. Nearly a century later in 1934, the United States government established the *Commodity Price Index* – initially recognising only 22

commodities – as they presumed these to be the first commodities influenced by economic conditions. Even in modern times, agricultural commodities can affect economies as uncontrollable circumstances, such as droughts, impact supply and demand.

Commodities in Modern Society

With the growth and development of financial markets in the late 20th and early 21st centuries, more than 3000 commodities are now recognised. In addition to the traditional mainstays, modern commodities include communications bandwidth, emissions credits, and crypto-currencies, to name just a few examples.

Commodities are distinguished by certain key characteristics. These provide a framework that can be used to understand and explore the nature of creativity. Commodities are: (a) *standardised*, in the sense that an ounce of gold is the same, whatever its provenance, and will attract the same price. The value of a commodity is not impacted by brand; (b) they serve as *inputs in a value-adding process*. Typically, little or no value is added to the commodity itself, however the commodity leads to the creation of value-added products and services; (c) commodities exist where there is a *market* of buyers and sellers. Supply and demand dictate the market, and the price, for commodities.

Can people, in the sense of their skills, knowledge and abilities, be regarded as commodities? Is human capital, in other words, a commodity? A simple example, manual human labour, serves to illustrate. In this example, the labour performed can certainly be regarded as an input to the production of value-added goods and services. It is largely standardised, in the sense that, in most countries, unskilled labour attracts a standard wage, regardless of who performs it, and the wage is usually dictated by supply and demand. When demand is strong, and the supply of unskilled labour is short, the price may rise, and vice versa. Little value is added to the commodity itself – unskilled labour requires no qualifications that would begin to create a differentiation between labourers. Of course, there are minor differences in the individuals performing the unskilled labour, but the key is that it is treated, by the market, as uniform and standardised.

In contrast to unskilled work, skilled human labour is rather different. The addition of skills, and the development of abilities, represents the addition of value, and leads to differentiation in the basic commodity. The underpinning commodity – the unskilled individual – is no longer standardised, such that one skilled individual may command a higher price or a higher wage than another. It appears, therefore, that the addition of skills and abilities creates something that is neither traditional commodity, nor *product*. The skilled individual, through some value-adding process (i.e. training or education), is no longer standardised, and yet remains something largely contributing to the development of goods and services, rather than an end – a product – in itself. Furthermore, it is the skill itself, for example, the ability to operate a forklift, the ability to perform complex arithmetic, and indeed, the ability to generate new and effective ideas (creativity), that is the key ingredient responsible for transforming a commodity into something that, while not necessarily a product or service, is *not* a commodity! (See [Table 1](#)). Human capital, in its *unskilled* form, is a commodity. Human capital, when developed, or skilled, becomes differentiated, and this departure from standardisation precludes it from being identified as a commodity.

Creativity as Commodity?

The preceding discussion raises some questions for creativity. In particular, what is the focus of any discussion on the commoditization of creativity? If an individual with the ability to generate and exploit novel ideas – a *creative individual*, in other words – is *skilled*, then it seems necessary to conclude that this cannot be regarded as an example of *creativity as commodity* ([Table 1](#)). However, is this sufficient to rule out creativity more broadly, or in other guises, as a commodity?

It seems natural to turn to the well-known 4Ps framework to delve deeper. Creativity is commonly held to be a function of the *Person* (in the sense of personality, motivation and feelings); the *Process* (in the sense of the underpinning convergent and divergent thinking employed in creativity); the *Press*, or environment, where creativity occurs; and the *Product*, or outcome, of a creative activity.

If we consider each of these in isolation – e.g. a Person with a constellation of traits, motivation and feelings favourable to creativity – it seems immediately apparent that such an individual is more than a commodity. The very fact that these qualities, such as openness to experience, a tolerance for ambiguity, and intrinsic motivation, appear in different individuals, in different proportions,

Table 1 The characteristics of commodities

Valuable?	✓	✓	✓	✓	✓
Developed?	×	✓	✓	✓	?

rules out this view of the Person as commodity. With respect to the personal qualities that favour creativity, individuals are not *standardised*.

Creativity often takes place in some sort of organisational setting. The Press (or environment) of any given organisation, like the Person, is highly differentiated. Some organisational settings are favourable to certain stages of creativity – idea generation, for example – while other settings are favourable to evaluation and validation. Like the Person, this natural variability in the environment of creativity once again leads to a lack of standardisation, and seems to rule out the creative Press as a commodity.

Is the Product view of creativity a manifestation of the commoditization of creativity? Among scholars there is widespread agreement that creativity is, at the very least, embodied in products that are both novel and effective. In other words, a creative product must be new, or original, or surprising, and, it must do what it is supposed to do. Regardless of other product criteria (for example, Cropley and Kaufman, 2012, describe elegance and genesis as additional qualities) the two *core* characteristics alone demonstrate that creativity is a property of an object, and, according to measurement theory (e.g. Cropley, 1997) admits by degrees. In other words, different products would be expected to have different levels of creativity (however this is assessed). If this is the case, then creative products cannot be commodities, because they are not standardised. If further evidence is needed, the fact that products are the result of the application of input commodities (raw materials and labour) also rules out product creativity as an aspect of the commoditization of creativity. In simple terms, commodities *lead to* products, creative or otherwise.

Is Process, then, a manifestation of creativity as commodity? Here, the situation is somewhat different from the preceding discussions. Since Guilford (1950), who spoke of ideational fluency and flexibility, and ideational novelty, a defining element of creativity has been the core process that is now widely defined as divergent thinking. The ability to generate many possible ideas from a single stimulus, in contrast to the process of searching for a single, correct answer (convergent thinking), has become almost synonymous with creativity. Both the manner in which this creative *process* is measured (for example, the Alternate Uses Test), and the criteria – fluency, flexibility, originality, and elaboration – used to assess divergent thinking (see Torrance, 1963) could be said to be highly standardised. Even broadening the discussion to a larger creative problem solving process, represented as a process of switching between convergent and divergent thinking (e.g. Guilford, 1959), results in a process that has remained remarkably stable – indeed, standardised – for over 60 years. If there is a candidate for creativity as commodity, Process may be the best fit (Table 2).

Creativity as a Complex System

One of the difficulties of any discussion of the commoditization of creativity is the underlying *systems* nature of creativity. Csikszentmihalyi (e.g. 1999) discusses creativity as a system, while Cropley et al. (2017) highlight the properties of a system in the context of creativity. Like any complex system, creativity cannot simply be reduced to its components, without losing the vital, emergent behaviour that results from the interaction of Person, Process, Press and Product.

While it may be the case that the creative Process – in the sense of the core divergent and convergent thinking skills – is a commodity (Table 1), when viewed as part of a complex system (Fig. 1), it is hard to make the case for the commoditization of creativity.

Fig. 1 shows that a creative Product is an emergent property of the system. The Product results from the interaction of a favourably disposed Person, equipped with (trained in) skills in divergent and convergent thinking, and operating in a supportive environment. Under these circumstances, we expect to see the generation of novel and effective (i.e. creative) products. In this *system*, only one element, Process, can be regarded as resembling a commodity. However, if some part of the system is not standardised, and is not a commodity, then it seems meaningless to treat the whole system as a commodity. Even though the system of creativity is valuable, and serves as an enabler of other outcomes, and even though the core process is essentially standardised, creativity as a whole is too highly differentiated to be a commodity.

Florida (2002) touched on a similar conclusion, albeit via a different pathway: “Thus, creativity has come to be the most highly prized commodity in our economy — and yet it is not a ‘commodity’. Creativity comes from people. And it annihilates the social categories we have imposed on ourselves. A Creative Economy requires diversity because every human is creative ... In doing so, it has pulled off yet another astonishing mutation: taking people who would once have been viewed as bizarre mavericks operating at the bohemian fringe and placing them at the very heart of the process of innovation and economic growth”.

Figure 1 The System of Creativity.

Conclusions

On the one hand, the core creative Process may resemble a commodity. On the other hand, it appears that creativity, as a system, is *not* a commodity. Does this matter, and does it impact on creativity theory and practice?

Commodities are raw materials. They are the inputs that, via value-adding processes, become solutions to problems. Gold is a commodity; it is a raw material extracted from the ground, and with little further processing, or development, is sold on the open market. Gold, in itself, is not a solution to a problem. It is, however, an input to a problem-solving process that can turn gold into, for example, a reflective coating for an astronaut's helmet.

Creativity, as the system of interacting elements (people, process, environment (press) and product) is not a commodity. It is not a *raw material*, and not a *natural resource* (which, by definition, exist without the actions of humankind). It is, rather, the differentiated and developed system that results in solutions to problems. Divergent thinking, in the sense of a standardised input, or *raw material*, may resemble a commodity. However, even that, with the proliferation of differentiated techniques, tools and methods (e.g. Brainstorming or Design Thinking) appears less and less like a commodity.

The question of the commoditization of creativity may be driven by an underlying desire to demonstrate the value of creativity. Commodities have value and are subject to supply and demand. When scarce, the value increases, and when plentiful, the value decreases. However, this view seems to be flawed when applied to creativity, for the simple reason that creativity is not a *zero-sum game*. The fallacy of regarding any aspect of creativity as a commodity can be seen in the following thought experiment: What if all people on Earth were trained in divergent thinking? In other words, what if there was an oversupply of divergent thinking? Would this render divergent thinking of no value? Of course not! Indeed, it is easier to imagine that more creative solutions would be generated, and that the perceived value of creativity would increase!

To repeat, creativity is not a zero-sum game; there is not a finite amount of creativity available to humankind. In fact, creativity may be better thought of as a *technology*. Pilzer (1990) describes this phenomenon through the concept of *economic alchemy*. He argued that a society's wealth is a function of the physical resources (i.e. commodities) available to it, with the *availability*, and value, of those physical resources determined by technology – "technology controls both the definition and the supply of physical resources" (p. 2). It follows, therefore, that "In fact, for the past few decades, it has been the backlog of unimplemented technological advances, rather than unused physical resources, that has been the determinant of real growth" (p. 2). This can be taken a step further by suggesting that it is a *lack of innovation* (i.e. *unexploited creativity*) that has prevented growth from reaching its real potential.

Creativity is an element of human capital. It exists in varying degrees in people and can be developed. It serves as a vital input to problem solving processes, giving it economic value. Creativity is, in fact, *much more* than a commodity.

Introduction

Why do some of the world’s most eminent creatives seem to be a little *off*, *different*, or even *crazy*? Notions of the “Mad Genius” hark back to times of Aristotle and Plato, forming a strong foundation for the assertion that creativity and psychopathology are somehow related. Both empirical and anecdotal evidence point to a compensatory advantage associated with genes that increase vulnerability to psychopathology: individuals with two dominant genes demonstrate severe psychopathological symptoms, but those with just one dominant gene often reap the benefits of increased creative capabilities.

Psychotic patients face many struggles, ranging from difficulties with maintaining employment to social isolation, low reproductive success, and a high risk of early death from suicide. Given these disadvantages, why have the genes associated with vulnerability to psychotic disorders not been selected out of the gene pool? Many researchers have proposed that the disadvantages of psychosis must be balanced by some advantages; in short, there must be some “good” that comes from genes related to psychosis, for otherwise they would no longer exist.

A similar conundrum can be found in the case of sickle-cell anemia, a condition in which there is a lack of healthy red blood cells to carry adequate oxygen throughout the body. Individuals homozygous (with two mutant genes) for sickle cell suffer from severe anemia and health issues that often result in early death. However, those who are heterozygous carriers (with one mutant gene and one normal gene) seldom suffer from symptoms—and benefit from an increased resistance to malaria. Thus, the threat of severe anemia in homozygous individuals is balanced by the benefit of resistance to malaria seen in heterozygous carriers. This *heterozygote advantage* is one explanation for the persistence of sickle-cell genes throughout generations, and several researchers have pointed to a similar advantage when investigating the convoluted relationship between creativity and psychopathology: “it is the presence of subclinical psychological characteristics associated with genetic liability or susceptibility to certain mental illnesses, rather than overt psychopathological symptomatology, that actually aid creativity” (Gostoli et al., 2017, p. 63). Such assertions are supported by numerous examples of eminent creatives who have suffered from severe mental disorders, leading to the conclusion that “madness may be the price for possessing one of the most sublime human gifts” (Barrantes-Vidal, 2004, p. 59).

Addressing the “Mad Genius” Stereotype

The “Mad Genius” controversy has historically been a polarizing issue among researchers. Indeed, humanistic and positive psychologists are quick to argue that creativity is a sign of superior mental health, or self-actualization. However, it is important to note that those who believe there is a relationship between creativity and psychopathology would likely question blunt claims that all creative geniuses are insane. *Rather than a direct correlation between creativity and psychosis, highly creative individuals share unique cognitive and dispositional traits with those who demonstrate vulnerability for mental or emotional instabilities.*

Lombroso's (1891/1985) work, *The Men of Genius*, investigated the relationship between creativity and the predisposition to mental illness. It suggested that genius was an evolutionarily beneficial form of insanity. A genetic link between creativity and psychosis reveals that relatives of the mentally ill are likely to carry mild forms of psychotic traits, which are thought to enhance creativity. Indeed, research has revealed that creative individuals are at a higher risk for various forms of psychopathology, such as mood disorders, schizophrenia spectrum disorders, substance abuse, ADHD, and autism.

Richards et al. (1988) were first to use the term "*compensatory advantage*" (p. 281) to describe the intriguing relationship between creativity and psychopathology. While others before Richards had proposed a connection between creativity and mood disorders, this team of researchers was the first to suggest that the *degree* of psychotic dysfunction was key to unraveling the "Mad Genius" phenomenon.

Evidentiary Support for Compensatory Advantage

Three main types of studies demonstrate that genes which increase vulnerability to psychopathology also provide a compensatory advantage for creativity: (1) historiometric studies, which systematically analyze archival data concerning eminent creatives throughout history; (2) psychiatric studies, which investigate the mental health of present-day creatives; and (3) psychometric studies, which rely on standard assessment instruments to measure both creativity and vulnerability to psychosis.

Historiometric Evidence

Historiometric studies systematically analyze the biographies of prominent creators, in search of symptoms similar to various psychopathological syndromes. Such research has revealed the rate and intensity of psychopathological symptoms to be higher among prominent creators than in the general population, the most notable difference in symptoms existing between high achieving artists and noncreative controls. One does not need to look far for examples of eminent creatives who fit this description. Take, for example, names such as Robin Williams, Vincent Van Gogh, Robert Schumann, Mozart, Beethoven, Sylvia Plath, Virginia Woolf, Anne Sexton, Ernest Hemingway, Edgar Allan Poe, Michelangelo, Georgia O'Keeffe, and Jackson Pollock. While these individuals are well-known for their impressive creative lifestyles and contributions, their lives also tell the story of mental struggles and instability.

Historiometric studies have generally provided convincing evidence for the posited relationship between creative achievement and mood disorders, the most notable being depression and correlates of alcoholism and suicide. Studies have revealed that creativity and mental illness seem to run in the same family lines; genealogies which produce some of the most eminent creators are intriguingly characterized by higher rates and intensities of psychopathological symptoms. Interestingly, historiometric studies have revealed that the intensity of mental illness symptoms varies with specific domains of creativity: one study revealed that British and Irish poets from 1705 to 1805 displayed mood disorders, suicide, and institutionalization at *twenty times* that of the normal population!

Psychiatric Evidence

Psychiatric research depends on the selection of prominent present-day creatives and the subsequent analysis of clinical diagnosis and therapeutic treatment of such individuals. As demonstrated by historiometric studies, such research has revealed a higher rate and intensity of psychotic symptoms associated with creative individuals, particularly those who express creativity in the artistic domain.

Investigations of some of today's most prominent writers have revealed a higher rate of mood disorders in these artists than in matched control groups. Furthermore, first-degree relatives of prominent creatives have been shown to be more likely to demonstrate characteristics of mood disorders and creative achievement than relatives of control subjects, suggesting that the "Mad Genius" trait could indeed be genetically heritable. One study revealed that first-degree relatives of hospitalized psychiatric patients were twice more likely than the normal population to be employed in creative professional fields.

Psychometric Evidence

Psychometric studies use standard assessment instruments (e.g., the Minnesota Multiphasic Personality Inventory and the Eysenck Personality Questionnaire) to assess vulnerability to psychosis in creative individuals. Creativity has been shown to positively correlate with psychoticism scores on the Eysenck Personality Questionnaire, and, once again, artistic creators demonstrate more elevated scores than scientific creators. Nonparanoid schizophrenia patients have traditionally scored higher than other groups on the 'unusual uses' test, which assesses the production of original and novel ideas. Research has also indicated that hypomanic and normal relatives score higher than manic-depressives and controls on the lifetime creativity scale.

Psychometric research is particularly informative, as evidence has revealed that the relationship between psychosis and creativity seems to lie on a continuum: eminent creatives often demonstrate a less severe form of psychosis, and thus are able to "take advantage" of being a carrier of these genes while avoiding the negative symptoms that occur with more extreme cases. Indeed, highly creative individuals typically score about midway between normal and abnormal ranges on tests of psychological symptoms.

Not All “Madness” Is the Same

It is important to note that the relationship between psychopathology and increased creative potential varies across specific types of mental disorders. Originally, the association between creativity and psychopathology was believed to mainly lie in the schizophrenic spectrum, but recent researchers argue creativity to be more clearly linked to the bipolar spectrum and mood disorders. Thus, very general statements such as “individuals with psychopathological disorders always benefit from increased creative potential” are much too general.

Explanations of the Compensatory Advantage Mechanism

Why does a mild hypomanic state benefit creative achievement? Various researchers have investigated the association between creativity and psychopathology, proposing unique terminology to expound upon the compensatory advantage mechanism.

The “Creativity Cluster”

Creative production is rooted in both the cognitive ability and emotional willingness to “think outside of the box”. [Simonton \(2005\)](#) proposed a “creativity cluster” of traits that equips individuals to engage in creative thought: defocused attention, divergent thinking, openness to experience, independence, and nonconformity. Several of these traits are also common among individuals vulnerable to psychopathology. For example, elevated scores on psychoticism are associated with both independence and nonconformity.

Eminent creatives are more likely to display traits in the “creativity cluster”, and thus likely to display traits indicative of psychopathology (of course, with the important caveat that psychopathological symptoms are not the sole source for the underlying cognitive and dispositional attributes of creativity). Indeed, research has revealed it is important not to conclude a causal relationship between psychopathology and creativity, but rather to maintain the assertion that the two share a common set of traits.

The Shared Vulnerability Model

The “dose-dependent” association between creativity and psychopathology asserts that mild doses of madness are beneficial to creativity, while heavier doses can be detrimental to creativity and life as a whole. Others have described this relationship as an inverted-U shape, emphasizing that creativity and psychopathology are positively correlated until the degree of psychopathology becomes so intense that it “overcomes” the individual, and the association with creativity weakens.

[Carson’s \(2011\)](#) Shared Vulnerability Model is consistent with the theory proposed by [Richards et al. \(1988\)](#) and implies that creativity and psychopathology share common genetic mechanisms which, depending on the presence or absence of protective factors, can manifest in a positive (enhanced creativity) or negative (psychopathic symptoms) manner. Research has demonstrated three main shared vulnerabilities: (1) reduced latent inhibition, (2) novelty seeking, and (3) neural hyperconnectivity.

Reduced Latent Inhibition

Latent inhibition is a filtering mechanism that screens irrelevant stimuli, thus focusing the mind on the most pressing and practical issues at hand. Research has shown low latent inhibition to be correlated with high creative achievement; the ability to simultaneously focus on relevant and irrelevant tasks leads to creative associations that often produce original ideas. In short, reduced latent inhibition brings more stimuli into the conscious awareness, increasing the supply of ideas and setting the stage for original and flexible thought. Eminent creatives have been shown to be seven times more likely to have reduced latent inhibition than noncreative counterparts, and research has also demonstrated an association between reduced latent inhibition and psychopathological syndromes.

Novelty Seeking

Novelty seeking is a common risk factor for psychopathology. Those who struggle with alcohol abuse and addiction are often driven to experience the “next new thing”, and research has shown that individuals with bipolar and substance abuse disorders score significantly higher on measures of novelty seeking than the control. Creatives are also likely to seek novel and complex stimuli; indeed, such an intrigue for the unknown may be the underlying motivational factor to attend to new ideas discovered partly due to reduced latent inhibition.

Neural Hyperconnectivity

Yet another shared vulnerability factor is neural hyperconnectivity. Such hyperconnectivity is common among schizophrenics and close relatives, and often thought to be the underlying mechanism for bizarre associations which are the characteristic symptom of the condition. Interestingly, hyperconnectivity is also common among creative individuals. Brain-imaging studies have revealed unusual patterns of connectivity among creatives, and the ability to synthesize such remotely associated ideas is thought to form the basis of creative production.

Protective Factors

What allows individuals to harvest the benefits of psychopathological syndromes, rather than letting the symptoms control them? Protective factors such as ego-strength, self-sufficiency, intelligence, and working memory capacity have been shown to exert control over psychopathological syndromes. For example, individuals with high IQs may be able to systematically process additional stimuli that result from reduced latent inhibition, while those with lower IQs are more likely to be overcome by such a surplus of stimuli and tend toward psychosis. Indeed, the combination of reduced latent inhibition and high IQ predicted an impressive 30% of the variance in creative achievement scores in Carson and his colleague's study of eminent creative individuals (Carson et al., 2003).

Working memory capacity may also serve as a protective factor; those with a higher capacity are able to attend to and process the surplus of stimuli which may result from altered states of consciousness that stem from reduced latent inhibition, mood disorders, or other psychopathic symptoms. Cognitive flexibility, closely related to the openness to experience trait that often characterizes creatives, may also equip individuals to successfully adapt to and utilize increased stimuli.

In further support of the importance of protective factors, research has revealed that while eminent creators demonstrate high psychopathology scores, they also demonstrate high levels of ego strength and advantages in both abstract and cohesive thinking.

Experiencing *Just Enough* “Madness” Increases Creativity

Put simply, there seems to be “sweet spot” between creativity and psychopathology: factors common to both creativity and psychopathology increase access to ideas being processed below conscious awareness, but protective factors exert executive monitoring and control over this access. Thus, individuals are able to take advantage of unusual (and often bizarre) thoughts, but not be overcome by them and drawn into madness. Indeed, many creative achievers prefer to tolerate mental symptoms, rather than take pharmaceuticals which they fear may lessen the creative ideas which result from minor forms of madness. As Richards (1996) claimed, “a-ha moments of creative insight often resemble an edge-of-chaos phenomenon” (p. 71).

Despite the seemingly polarizing nature of the “Mad Genius” debate, there is a general consensus that less severe cases of psychopathology are associated with creativity. The concept of compensatory advantage (and the alternative labels for it) provide an explanation for why subclinical levels of certain forms of psychopathology are related to creativity. It might be that the notion of a “Semi-Mad Genius” would be more accurate than “Mad Genius”!

Many people believe that creativity benefits from competition, the activity or condition of striving to gain or win something by defeating or establishing superiority over others. This is reflected in the many contests or awards to procure creative ideas and innovative products. For instance, science foundations stimulate competition among scientists by awarding grants to the most promising research proposals; the online television company Netflix created a \$1 million prize for innovations that would improve the accuracy of its movie recommendation algorithm by 10%; and companies increasingly use open innovation tournaments where people can win prizes with their suggested problem solutions. The idea that competition fosters creativity is also fueled by anecdotal evidence that rivalry was at the basis of creative genius, for instance for the musicians Lennon and McCartney and the scientists Max Perutz, James Watson, and Francis Crick.

Notwithstanding the popular belief that competition promotes creativity, empirical research on the effects of competition on creativity reveals mixed findings. Some research findings demonstrate that people are more creative when competing with each other (e.g., [Beersma and De Dreu, 2005](#); [Chen and Chiu, 2016](#)). However, other studies found that competition negatively impacts creativity ([Amabile, 1996](#); [Erat and Gneezy, 2016](#)). Even more commonly, neither positive nor negative main effects of competition on creative performance are obtained (e.g., [Baer et al., 2013](#); [Baas et al., 2019](#); [Zhu et al., 2018](#)).

Further complicating the question whether competition is beneficial or detrimental to creativity is that this question may be answered at different levels of analysis; competition may have different effects for individual creativity than for group-level creativity. This suggests that rather than simply asking the question whether competition fosters creativity, we should instead ask when and for whom competition promotes or prevents creativity. The goal of this Encyclopedia entry is to provide answers to the latter question. This entry reviews the effects of competition at the individual and group level and identifies moderators that determine the sign and size of the effect of competition on creativity. The literature is summarized by discussing broad trends and developments.

Competition at the Individual Level

When Competition Motivates Reduced or Enhanced Creativity

Theories that predict a negative effect of competition emphasize that competition triggers the “wrong” motivation. Whereas creativity benefits most from intrinsic motivation, in which the creative act is enjoyed, interesting, and an end in itself ([Amabile, 1996](#)), competition leads to extrinsic motivation, driving people to engage in a creative act to pursue an ulterior end (e.g., a prize, status; [Amabile, 1996](#)). This increases feelings of being controlled and may lead to distraction by the prize or opponent, hampering creativity ([Amabile, 1996](#)). The detrimental effects of competition-induced extrinsic motivation on creativity have been demonstrated in a classic study among children by Amabile in 1982. Children generally enjoy creating and building. Non-competing children, that were intrinsically motivated, built more creative paper collages than extrinsically motivated children, that were competing with each other for prizes (see [Amabile, 1996](#) for a discussion of this study). This negative effect of competition on creativity has been replicated in other samples and with different tasks (e.g., [Amabile, 1996](#); [Erat and Gneezy, 2016](#)).

Theory that predicts positive effects of competition on creativity is based on the rationale that competition motivates people to increase their effort ([Eisenberger and Rhoades, 2001](#)). Indeed, creativity often involves hard work, takes time, and requires perseverance ([Baas et al., 2019](#)). Crucially, [Eisenberger and Rhoades \(2001\)](#) argued that it is essential that competing people know where

[☆] All authors declare that they have no conflict of interest.

to direct their efforts by informing them what specific type of performance is expected and valued. For instance, when specific performance criteria are absent, children making collages could focus on neatness instead of originality. However, when competing people know that creative performance is expected and valued, they can steer their effort and activities to meet this criterion, and competition should then foster creativity. This is indeed what studies on the effects of rewards on creativity show: Competition improves creativity when the reward is contingent on creative performance (e.g., [Eisenberger and Rhoades, 2001](#)).

Innovation contests are a specific type of competition where competitors know that creative performance is desired. In innovation contests, a company posts a problem to problem solvers. The problem solvers, either individuals or teams, submit plans or prototypes to the company and the best plan or prototype receives an award. Innovation contests work well to procure creative solutions. Importantly, in designing the contest, companies must decide how many problem solvers may compete. Increasing the number of competitors reduces the likelihood of winning for each problem solver. This increased rivalry reduces the incentives to invest effort and thereby lowers overall creative performance: Economists even argue that contests should be limited to two problem solvers to minimize underinvestment of effort ([Terwiesch and Xu, 2008](#)). However, a large number of problem solvers also increases the diversity of solutions and the likelihood of at least one good solution ([Terwiesch and Xu, 2008](#)). Moreover, this is especially the case when the problem is ill-structured and uncertain. Thus, the nature of the problem should be explicitly considered in designing innovation contests.

Although competition may foster creativity when it is clear that creative performance is desired, this beneficial effect may depend on whether men or women compete. Because women are less responsive to incentivized competition than men ([Erat and Gneezy, 2016](#)), gender represents an important moderator. Indeed, research findings show that whereas women were less creative in competitive situations, the creativity of males was either unaffected or enhanced in competitive situations (e.g., [Erat and Gneezy, 2016](#)).

In sum, whether competition improves or prevents creativity, or has no effect, depends on several factors: When people feel they are being extrinsically controlled by the competition, this reduces creativity. When performance criteria are specifically aimed at creativity, this increases creativity. Finally, gender moderates the effects of competition on creativity, with more negative effects for females than for men. However, the effect of competition on creativity may also depend on the type of creativity, a possibility that is explored next.

Malevolent Creativity

Creativity is often beneficial, however, people also generate novel ways to harm and hurt ([Baas et al., 2019](#)). Examples of malevolent creativity include data fabrication of scientists, dirty tricks in political campaigns and firms falsifying information. Provocative and threatening circumstances trigger malevolent creativity ([Baas et al., 2019](#)), so it is likely that competition increases creative malevolent responses.

Anecdotes support this notion. For example, to compete with Virgin Atlantic, British Airways resorted to dirty tricks, which included circulating rumors that Virgin CEO Richard Branson had HIV and telling Virgin's customers that their flights had been canceled. In addition, the fierce competition in science leads some scientists to perform biased peer review, sabotage competitors, and engage in questionable research practices.

There is also empirical support that competition breeds malevolent creativity. In studies conducted in our lab, people who were engaged in a competitive game against another person came up with more malevolent uses for a brick (e.g., using a brick as a weapon, or to sink a body) than non-competing others (see e.g., [Baas et al., 2019](#)). Together, these findings suggest that competition may also fuel a much darker side of creativity by facilitating the generation of ideas that are malevolent in nature.

Beyond Idea Generation

Most work on the competition-creativity link focuses on idea generation. However, following the idea generation stage, people must decide which idea or product to pursue and which to abandon, and ideas or products should ultimately be implemented. Although empirical research is sorely needed, some theoretical propositions have already been put forward. [Goncalo and Krause \(2010\)](#) proposed that competition may diminish idea selection performance, arguing that in a competitive climate, group members may derogate each other's ideas and refuse to compromise. It is also proposed that competition may diminish creative idea generation but enhance innovation implementation, because the need for innovation is perceived to be stronger. An important direction for future research would be to examine how competition impacts each stage of the creative journey, from the genesis of a creative idea to its ultimate implementation.

Competition as a Mindset

The studies in the previous sections examined the creative performance of people in competitive situations. Rather than being immersed in competition, people can also have a competitive mindset, i.e. more generally strive for individual achievement and to outperform others (also labeled performance approach orientation; e.g., [Goncalo and Krause, 2010](#)). Such a competitive mindset is positively related to self-perceptions of one's ability to generate creative ideas. A competitive mindset may foster creativity through this increased creative self-efficacy. Indeed, [Beersma and De Dreu \(2005\)](#) showed that competitive versus cooperative mindsets developed during a negotiation task influenced post-negotiation performance; those with a competitive mindset generated more

original advertisement slogans in a post-negotiation task. In addition, people with a stronger competitive mindset tend to produce more creative ideas (see [Goncalo and Krause, 2010](#) for an overview).

Although a competitive mindset may suffice for creativity when people work privately on fun tasks, additional requirements may be needed when working in the real world. In an organizational context, people work on real problems with more at stake and they have to overcome obstacles. Indeed, research often fails to find a main effect of a competitive mindset on creativity in field settings. However, a competitive mindset does appear to be positively related to creativity when people work in teams where learning and reflection is emphasized or work in organizations where rules are relatively unclearly specified and procedures unstandardized (e.g., [Hirst et al., 2011](#)).

In summary, competitive mindsets seem to increase the creativity of generated ideas, but in field settings, mixed results have been found regarding the impact of competitive mindsets.

Competition at the Group Level

Intragroup Competition

Creative performance in groups depends on the creativity of the input of individual group members and the way group members share, process, integrate, and build on this input to shape new ideas ([Hülsheger et al., 2009](#)). When individual performance within a group gets rewarded (henceforth intragroup competition), the creative input of individual group members may increase through an enhanced motivation to be more creative than everyone else in the group. Competition thus facilitates creativity in groups by motivating individuals to match or exceed the performance of highly creative group members. Related to this rationale, [Zhu et al. \(2018\)](#) observed that a competitive team climate did not significantly relate to creativity, but that it did positively predict extrinsic motivation. This, in turn, was associated with enhanced creativity for team members who had low intrinsic motivation. Intragroup competition could thus be effective when the creative project does not create interest on its own.

However, these beneficial effects of intragroup competition may be limited to conditions of low task interdependence. When the creative task requires the different group members to share knowledge, exchange ideas, and integrate their different perspectives, group creativity requires enhanced collaboration, cohesion, communication, and the constructive and open discussion of ideas ([Hülsheger et al., 2009](#)). Intragroup competition could disrupt these processes (e.g., [Amabile, 1996](#)): it leads to reduced collaboration among group members and a greater fear of being ridiculed by others. It also leads to a greater reluctance to share ideas and a rejection of knowledge by rivaling group members.

This is why [Amabile \(1996\)](#) identified destructive internal competition as an impediment for organizational creativity. In other studies, intragroup competition appeared to be unrelated or negatively related to group creativity. For instance, [Černe et al. \(2014\)](#) found that competitive rivalry in groups was negatively related to the creativity of individuals who tended to hide knowledge and information from other group members. In sum, intragroup competition can stimulate group members' extrinsic motivation and as such foster creative performance at the group level. However, this positive impact of competition seems limited to task contexts characterized by low interdependence. When creative performance requires group members to exchange and integrate information, competition reduces creative performance. Recent studies showed that some team members seem to suffer more from the latter effects than others, and an intriguing direction for future research would be to examine how intragroup competition may be structured to reap its' positive, but not negative effects.

Intergroup Competition

To spur creativity, companies often have different teams compete with each other. This intergroup competition increases effort in teams and leads to more unity, collaboration, and information exchange among group members ([Baer et al., 2010](#)), all processes that are conducive to creativity. [Chen and Chiu \(2016\)](#) indeed showed that partnering students competing with other groups were more engaged and creative than those that were not competing. [Baer et al. \(2010\)](#) also found that effects on creativity were positive for low to moderate intergroup competition, but then plateaued when competition became increasingly fierce. Apparently, intergroup competition pushes groups to be more collaborative and creative up to a certain point.

However, other findings suggest that performance-effects of intergroup competition depend on contextual factors and group composition. For instance, because men are more responsive to competition than women, [Baer et al. \(2013\)](#) showed that having groups compete against one another is stimulating to the creativity of groups composed mostly or exclusively of men but detrimental to the creativity of groups composed largely or exclusively of women. Moreover, [Baer et al. \(2010\)](#) uncovered that effects of intergroup competition on creativity were largely positive in static groups (groups in which no change in groups' membership occurs), but followed a U-shaped relation with creativity in fluid groups where groups exchanged a member with a competing group. The authors explained the latter finding by arguing that groups find it more difficult to adopt a collaborative mind-set toward past competitors than to shift from a collaborative to a competitive mind-set. This idea is supported by findings by [Beersma et al. \(2009\)](#) that showed that creating cooperation between former adversaries was more difficult than having former cooperators compete. The findings by Baer and colleagues also imply that a comprehensive understanding of the effects of intergroup competition on creativity requires the consideration of nonlinear effects.

As a final consideration, from an organizational perspective, it is difficult to imagine a structure where intergroup competition would not in the long run hurt organizational performance. Having groups, teams or departments compete with one another

presumes that they operate independently. With today's increasingly complex environment, this assertion becomes difficult to uphold. Longitudinal studies that assess the long-term effects of intergroup competition are currently lacking, but would be very worthwhile to shed light on the benefits and detriments of this type of competition over time.

Conclusions

The effects of competition on creativity depend on several factors. At the individual level, competition tends to lead to reduced creativity for women and if people's intrinsic motivation is undermined. Competition tends to lead to enhanced creativity for men, if creativity is a clear performance criterion, if people have competitive mindsets and if the content of ideas is malevolent in nature. At the group level, competition within groups may spur the creativity of individual group members, but is unlikely to have positive effects when group creativity relies on active collaboration and sharing of information and perspectives. Competition between groups tends to raise group creativity.

Future studies should examine the effects of competition on creative performance over time, in ongoing teams, and should examine the factors that help groups to reap the benefits of competition without suffering from its detriments. In any case, the current entry demonstrates that there is much more to the competition-creativity link than lay wisdom suggests.

Glossary

Component In the context of this article, one of the elements that in some combination constitute creativity in a person or product

Domain An area of creative endeavor, such as physics or painting. There is no generalized agreement as to what the domains of creativity are

Intelligence The ability to learn and to adapt to environments

Knowledge The organized body of information that serves as a jumping-off point for creative thinking. It is a prerequisite to creative thinking

Motivation One's level of involvement in an activity; the energy one brings to one's creative or other activities

Style A preference in the use of one's thinking or learning

Definition of Componential Models

A componential model of creativity is basically one that seeks to specify the basic components, or elements, that work together to produce creative behavior. Some works on creativity hypothesize that multiple components must converge for creativity to occur (Sternberg et al., 2004).

[☆] *Change History:* January 2019. Robert Jeffrey Sternberg updated the text throughout the article.

This article is an update of R.J. Sternberg, Componential Models of Creativity, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 226–230.

Components Derived From Folk (Implicit) Conceptions of Creativity

Robert Sternberg (1985), for example, examined laypersons' and experts' conceptions of the creative person. People's implicit theories contain a combination of cognitive and personality elements, such as "connects ideas," "sees similarities and differences," "has flexibility," "has aesthetic taste," "is unorthodox," "is motivated," "is inquisitive," and "questions societal norms." This work suggests that the basic components of creativity are not to be found within any single branch of psychology or any other field – cognition, personality, or social psychology, for example – but rather cross these different branches.

On the one hand, lay theories of psychological phenomena are useful because they give us some insight into how people make judgments about creativity in their everyday lives. How do they assess not only other people's creativity, but also their own? On the other hand, lay theories lack the benefit of the expertise that researchers on creativity can provide, as illustrated below.

Components Derived From Explicit Theories of Creativity

Amabile

At the level of explicit theories, Teresa Amabile (1996) and her colleagues have described creativity as the confluence of intrinsic motivation, domain-relevant knowledge and abilities, and creativity-relevant skills. The creativity-relevant skills include:

- (1) a cognitive style that involves coping with complexities and breaking one's mental set during problem solving;
- (2) knowledge of heuristics for generating novel ideas, such as trying a counterintuitive approach; and
- (3) a work style characterized by concentrated effort, an ability to set aside problems, and high energy. An important feature of this model is that it points out that creativity involves styles as well as abilities – that is, preferences in ways of thinking. It also points out the importance of sheer hard work in achieving creative solutions to problems.

Baer and Kaufman

John Baer and James Kaufman (2010) have proposed an amusement-park model of creativity, wherein the researchers analogize the components of creativity to the components of moving around through an amusement park. For example, one has to pick a section of the amusement park in which to walk and then has to pick specific things to do within the amusement park, just as one has to pick a domain in which to do creative work and then a specific problem or set of problems within that domain.

Gruber

The late Howard Gruber (1974) and his colleagues proposed a developmental *evolving-systems model* for understanding creativity. A person's knowledge, purpose, and affect grow over time, amplify deviations that an individual encounters, and lead to creative products. Developmental changes in the knowledge system have been documented in cases such as Charles Darwin's thoughts on evolution. Purpose refers to a set of interrelated goals, which also develop and guide an individual's behavior. Finally, the affect or mood system notes the influence of joy or frustration on the projects undertaken. Gruber's model emphasizes that components of creativity cannot be understood merely additively. That is, one cannot simply list components and ask a person whether he or she is at some reasonably high level on some or all of them. Rather, one must look at how they interact systemically in order to determine whether a person does and is likely in the future to continue to produce creative work.

Csikszentmihalyi

Mihalyi Csikszentmihalyi (2013) took a different "systems" approach and highlighted the interaction of the individual, domain, and field. An individual draws upon information in a domain and transforms or extends it via cognitive processes, personality traits, and motivation. The field, consisting of people who control or influence a domain (e.g., art critics and gallery owners), evaluates and selects new ideas. The domain, a culturally defined symbol system such as alphabetic writing, mathematical notation, or musical notation, preserves and transmits creative products to other individuals and future generations.

Gardner

Other work complements that of Csikszentmihalyi. Howard Gardner (2011) and his various colleagues over the years conducted case studies suggesting that the development of creative projects may stem from an anomaly within a system (e.g., tension between competing critics in a field) or moderate asynchronies between the individual, domain, and field (e.g., unusual individual talent for a domain). In particular, Gardner analyzed the lives of seven particular individuals who made highly creative contributions in the twentieth century, with each specializing in one of the multiple intelligences: Sigmund Freud (intrapersonal), Albert Einstein (logical-mathematical), Pablo Picasso (spatial), Igor Stravinsky (musical), T. S. Eliot (linguistic), Martha Graham (bodily-

kinesthetic), and Mohandas Gandhi (interpersonal). Charles Darwin would be an example of someone with extremely high naturalist intelligence. Gardner pointed out, however, that most of these individuals actually had strengths in more than one intelligence, and that they also had notable weaknesses in others (e.g., Freud's weaknesses may have been in spatial and musical intelligences). In the case of Gardner's model, the components are not so much additive as threshold determined. That is, the outstanding individuals Gardner cites are all people who excelled in one of the components of Gardner's model. They were not necessarily distinguished or even good at other components. For example, there is no reason to believe that Martha Graham would have excelled as a physicist, or Einstein, as a dancer!

Although creativity can be understood in terms of uses of the multiple intelligences to generate new and even revolutionary ideas, Gardner's analysis goes well beyond the intellectual. For example, Gardner pointed out two major themes in the behavior of these creative giants. First, they tended to have a matrix of support at the time of their creative break-throughs. Second, they tended to drive a "Faustian bargain," whereby they gave up many of the pleasures people typically enjoy in life to attain extraordinary success in their careers. However, it is not clear that these attributes are intrinsic to creativity, *per se*; rather, they seem to be associated with those who have been driven to exploit their creative gifts in a way that leads them to attain eminence. Gardner further followed the path of collaborator Csikszentmihalyi in distinguishing between the importance of the domain (the body of knowledge about a particular subject area) and the field (the context in which this body of knowledge is studied and elaborated, including the persons working with the domain, such as critics, publishers, and other "gatekeepers"). Both are important to the development, and ultimately, the recognition of creativity.

Sternberg and Lubart

A confluence theory also was proposed by Robert Sternberg and Todd Lubart's (1995) *investment theory of creativity*. According to this theory, creative people are ones who are willing and able to "buy low and sell high" in the realm of ideas. Buying low means pursuing ideas that are unknown or out of favor but that have growth potential. Often, when these ideas are first presented, they encounter resistance. The creative individual persists in the face of this resistance, and eventually sells high, moving on to the next new or unpopular idea.

Research within the investment framework has yielded support for this model. Some of this research has used cognitive tasks such as (1) writing short stories using unusual titles (e.g., "the octopus' sneakers"), (2) drawing pictures with unusual themes (e.g., "the earth from an insect's point of view"), (3) devising creative advertisements for boring products (e.g., cufflinks), and (4) solving unusual scientific problems (e.g., how we could tell if someone had been on the moon within the past month). This research showed creative performance to be moderately domain specific, and to be predicted by a combination of six distinct but interrelated resources: intellectual abilities, knowledge, styles of thinking, personality, motivation, and environment.

Sternberg and colleagues showed that it was possible to distinguish a factor for creative thinking from factors for analytical and practical thinking. Including creative items in assessments for college admissions increased prediction of freshman-year success in college and also reduced relative differences among students of different ethnic groups. Subsequent work showed that measures of creativity improved not only prediction of academic work, but also of meaningful participation in extracurricular activities.

In more recent work, Sternberg (2018) expanded his conception of components of creativity to include not only defiance of the crowd, but also defiance of the self and defiance of the Zeitgeist. In this triangular theory of creativity, people are creative to the extent that they can stand up to what others think; stand up to their own past beliefs; and stand up to their preconceptions of what the world must be like.

Rhodes

Mel Rhodes (1961) proposed early on that creativity could be understood within a four-P framework. The four P's are product, person, process, and press. The product, of course, refers to the creative idea or artifact that is judged to be novel as well as appropriate for some purpose. The person refers to the creator of the idea or artifact. The process refers to the way in which the creative act came to be—the mental steps involved. And press refers to the external pressures acting on a person, either to produce more or less creative ideas or artifacts.

Glaveanu

Vlad Glaveanu (2013) recently has proposed a "five A's framework" for understanding creativity that, in some ways, elaborates on Rhodes' framework. He has argued that each "A" in essence serves as a separate but interrelated component of the creative process. The first component is the actor, or the person who produces the creative product. But although creativity is often studied in the context of the person, the person is not sufficient for understanding creativity. One also must understand the action—or what it is that the creator does, and how he or she does it. Further, one must understand the artifact that the actor produces through his or her action. What is it about the artifact that makes it creative? Next one must understand the audience that makes the judgment as to what is creative, because creativity is always judged in a sociocultural context. Artifacts are not creative in themselves, but rather, in the context in which they are judged. And finally, one must understand the affordances, or

aspects of the environment, that allow (or do not allow) creativity to occur. What kinds of circumstances give rise to creativity, or the absence thereof?

James, Taylor, and Colleagues

James et al. (1999), James and Taylor (2010, and later Sternberg 2019 have distinguished among positive creativity, negative creativity, and neutral creativity. Their suggestion is that we must recognize that merely valuing creativity for its own sake is naive. Although creativity can be used for good ends, it also can be used for bad and even evil ends. Cropley and Cropley further have discussed the concept of malevolent creativity: Sometimes creativity is used to accomplish bad ends. It is important that, in understanding creativity, we seek to understand what components make creativity either positive or negative in its outcomes. Gardner, Csikszentmihalyi, and Damon have made a similar point in their discussion of good work.

General Aspects of Componential Theories

In general, confluence theories of creativity offer the possibility of accounting for diverse aspects of creativity. For example, analyses of scientific and artistic achievements suggest that the median rated creativity of work in a domain tends to fall toward the lower end of the distribution and the upper – high creativity – tail extends quite far. This pattern can be explained through the need for multiple and often diverse components of creativity to co-occur in order for the highest levels of creativity to be achieved. As another example, the partial domain specificity of creativity that is often observed can be explained through the mixture of some relatively domain-specific components for creativity, such as knowledge, and other more domain-general components, such as, perhaps, the personality trait of perseverance.

The various theories described above suggest at least six distinct but interrelated resources: intellectual abilities, knowledge, styles of thinking, personality, motivation, and environment. Although levels of these resources are sources of individual differences, often the decision to use the resources is the more important source of individual differences.

Intellectual Abilities

Three intellectual skills are particularly important: (a) the synthetic ability to see problems in new ways and to escape the bounds of conventional thinking; (b) the analytic ability to recognize which of one's ideas are worth pursuing and which are not; and (c) the practical-contextual ability to know how to persuade others of – to sell other people on – the value of one's ideas. The confluence of these three abilities is also important. Analytic ability used in the absence of the other two abilities results in powerful critical, but not creative thinking. Synthetic ability in the absence of the other two abilities results in new ideas that are not subjected to the scrutiny required to make them work. And practical-contextual ability in the absence of the other two may result in the transmittal of ideas not because the ideas are good, but rather, because the ideas have been well and powerfully presented. To be creative, one must first *decide* to generate new ideas, analyze these ideas, and sell the ideas to others.

Put another way, one first needs to be creative—to come up with a new idea. But once one comes up with an idea, one further has to use analytical skills to decide whether the idea is a good one. And finally, one has to use practical skills to convince other people of the worth of the idea.

Some studies have sought to test the role of intelligence in creativity through a variety of studies. Sternberg and colleagues presented 80 individuals with novel kinds of reasoning problems that had a single best answer. For example, they might be told that some objects are green and others blue; but still other objects might be *grue*, meaning green until the year 2000 and blue thereafter; or *bleen*, meaning blue until the year 2000 and green thereafter. Or they might be told of four kinds of people on the planet Kyrion: *blens*, who are born young and die young; *kwefs*, who are born old and die old; *balts*, who are born young and die old; and *prosses*, who are born old and die young. Their task was to predict future states from past states, given incomplete information. In another set of studies, 60 people were given more conventional kinds of inductive reasoning problems, such as analogies, series completions, and classifications, but were told to solve them. But the problems had premises preceding them that were either conventional (dancers wear shoes) or novel (dancers eat shoes). The participants had to solve the problems as though the counterfactuals were true.

In these studies, Sternberg and his colleagues found that correlations with conventional kinds of tests depended on how novel or nonentrenched the conventional tests were. The more novel the items, the higher the correlations of our tests with scores on successively more novel conventional tests. Thus, the components isolated for relatively novel items would tend to correlate more highly with more un-usual tests of fluid abilities than with tests of crystallized abilities. Sternberg and his colleagues also found that when response times on the relatively novel problems were componentially analyzed, some components better measured the creative aspect of intelligence than did others. For example, in the “grue–bleen” task mentioned above, the information-processing component requiring people to switch from conventional green–blue thinking to grue–bleen thinking and then back to green–blue thinking again was a particularly good measure of the ability to cope with novelty.

Other studies by Donald McKinnon and Frank Barron have suggested that there is a threshold effect for the role of intelligence in creativity. They suggested that intelligence is moderately correlated with creativity up to an IQ of about 120, but that after that, the

two constructs are largely unrelated. More recently, however, David Lubinski and Camilla Benbow have argued that the relation between intelligence and creativity remains moderate to strong throughout the entire range of IQ.

Knowledge

Concerning knowledge, on the one hand, one needs to know enough about a field to move it forward. One cannot move beyond where a field is if one does not know where it is. On the other hand, knowledge about a field can result in a closed and entrenched perspective, resulting in a person's not moving beyond the way in which he or she has seen problems in the past. Thus, one needs to decide to use one's past knowledge, but also decide not to let the knowledge become a hindrance rather than a help.

Work by Robert Weisberg and David Perkins has suggested that knowledge plays a strong role in creativity. They have found that when more creative people are compared to less creative ones, a major difference is in the depth and breadth of their respective knowledge bases. Peter Frensch and Robert Sternberg have suggested, however, that expertise can lead to entrenchment, and hence that experts who are very knowledge-able can become susceptible to being less creative because they are used to thinking in traditional ways.

Thinking Styles

With regard to thinking styles, one kind of style is particularly important for creativity, namely, a preference for thinking and a decision to think in new ways. Sternberg has referred to this as a "legislative style." John Cacioppo has spoken of need for cognition. Joseph Fagan has found that even infants can differ in their preferences for novelty. This preference needs to be distinguished from the ability to think creatively: someone may like to think along new lines, but not think well, or vice versa. It also helps, to become a major creative thinker, if one is able to think globally as well as locally, distinguishing the forest from the trees and thereby recognizing which questions are important and which ones are not.

Personality

Numerous research investigations by Frank Barron, Donald MacKinnon, and others have supported the importance of certain personality attributes for creative functioning. At one time, the Institute for Personality Assessment Research at the University of California, Berkeley, was devoted to uncovering the personality traits linked to creative performance. These attributes include, but are not limited to, willingness to overcome obstacles, willingness to take sensible risks, willingness to tolerate ambiguity, and self-efficacy. In particular, buying low and selling high typically means defying the crowd, so that one has to be willing to stand up to conventions if one wants to think and act in creative ways. Note that none of these attributes are completely fixed. One can *decide* to overcome obstacles, take sensible risks, and so forth. However, there can be little doubt that people differ in their general predispositions toward the personality attributes of creative thought.

The most important characteristic for creativity may well be a willingness to formulate problems for oneself rather than to accept the formulations of others. Once one accepts others' formulations, one often comes to the same conclusions that the others did. But many great creative discoveries, such as the importance of bacteria in causing illness, came about because scientists looked for entirely new mechanisms of causality rather than merely asking how those mechanisms already identified, such as "miasma" (bad smells or foul-smelling vapors), might work (in this case, to cause illness).

Motivation

Intrinsic, task-focused motivation is also essential to creativity. The research of Teresa Amabile (1996), Beth Hennessey 2019, and others has shown the importance of such motivation for creative work, and has suggested that people rarely do truly creative work in an area unless they really love what they are doing and focus on the work rather than the potential rewards. Motivation is not something inherent in a person: One decides to be motivated by one thing or another. However, the environment, discussed below, can play a major role in motivating people in one direction or another.

Environment

Finally, one needs an environment that is supportive and rewarding of creative ideas. One could have all of the internal resources needed in order to think creatively, but without some environmental support (such as a forum for proposing those ideas), the creativity that a person has within him or her might never be displayed. Teresa Amabile has found that in environments that do not encourage creativity, creativity is much rarer than in supportive environments.

Confluence

Concerning the confluence of components, creativity is hypothesized to involve more than a simple sum of a person's level on each component. First, there may be thresholds for some components (e.g., knowledge) below which creativity is not possible regardless of the levels on other components. Second, partial compensation may occur in which a strength on one component (e.g.,

motivation) counteracts a weakness on another component (e.g., environment). Third, interactions may also occur between components, such as intelligence and motivation, in which high levels on both components could multiplicatively enhance creativity.

Components of Creative Products

Robert Sternberg et al. (2002) have proposed that not only persons, but products, can be understood in terms of different components.

First, some kinds of creativity accept current paradigms or try to extend them.

1. *Replication*. The contribution is an attempt to show that the field is in the right place. The propulsion keeps the field where it is rather than moving it. This type of creativity is represented by stationary motion, as of a wheel that is moving but staying in place.
2. *Redefinition*. The contribution is an attempt to redefine where the field is. The current status of the field thus is seen from different points of view. The propulsion leads to circular motion, such that the creative work leads back to where the field is, but as viewed in a different way.
3. *Forward incrementation*. The contribution is an attempt to move the field forward in the direction it already is going. The propulsion leads to forward motion.
4. *Advance forward incrementation*. The contribution is an attempt to move the field forward in the direction it is already going, but by moving beyond where others are ready for it to go. The propulsion leads to forward motion that is accelerated beyond the expected rate of forward progression.

Second, other types of creativity reject current paradigms and attempt to replace them or put them together in some way.

5. *Redirection*. The contribution is an attempt to redirect the field from where it is toward a different direction. The propulsion thus leads to motion in a direction that diverges from the way the field is currently moving.
6. *Reconstruction/redirection*. The contribution is an attempt to move the field back to where it once was (a reconstruction of the past) so that it may move onward from that point, but in a direction different from the one it took from that point onward. The propulsion thus leads to motion that is backward and then redirecive.
7. *Reinitiation*. The contribution is an attempt to move the field to a different as yet unreached starting point and then to move from that point. The propulsion is thus from a new starting point in a direction that is different from that the field previously has pursued.
8. *Synthesis*. The contribution attempts to move the field by putting together ideas from a variety of paradigms and integrating them into a single conceptual framework.

The eight types of creativity described above are viewed as qualitatively distinct. However, within each type, there can be quantitative differences. For example, a forward incrementation can represent a fairly small step forward, or a substantial leap. A reinitiation can restart a subfield (e.g., the work of Leon Festinger on cognitive dissonance) or an entire field (e.g., the work of Einstein on relativity theory). Thus, the theory distinguishes contributions both qualitatively and quantitatively.

Domain Generality Versus Domain Specificity of Components of Creativity

An important question is whether the components of creativity are domain general or domain specific. The greatest challenge in understanding the domain generality versus specificity of creativity is in understanding the concept of a domain itself. Is literature a domain, or German literature, or modern German literature, or modern German literature in its original language, or what? Is cognitive psychology a domain, or psychology, or behavioral science, or social science? Because we have no good definition of a domain, we cannot, at this point in time, have a clear sense of exactly what domain-specificity means. Here, we recognize that domains may themselves be defined at varying levels of generality or specificity. There is not, at this time, any consensual definition of a domain.

First, creativity is, in part, an attitude toward life. This attitude can but does not necessarily extend across a variety of domains. That is, someone might adopt the mindsets that lead to creative thinking across domains, but they do not necessarily do so. Whether they do so or not will be one factor in determining the extent to which creativity is domain-general for a given individual. For example, one such attitude is that creative ideas do not necessarily sell themselves, and hence it often is necessary to sell one's creative ideas. One might adopt this attitude, say, in one's work, but not in one's personal life, or vice versa. Even within one's work environment, one might adopt this mindset, say, in one's interactions with objects but not with people, or vice versa. So domain generality will be a function of the extent to which an individual thinks with a creative mindset across domains. More of these mindsets will be described shortly.

Much of the attitudinal effect is captured through what was called above a *legislative style* of intellectual inquiry. A person with a legislative style is someone who enjoys coming up with new ideas. The ability to generate new ideas does not necessarily go along with a desire to generate such ideas. Someone may be more comfortable in thinking in traditional ways, even if he or she has the ability to think nontraditionally. In this case, the issue is not how well one can think creatively, but rather, how much one desires to think in this way. This desire may be mediated, in part, by socialization. In some societies and some religions, creativity is

discouraged. The individual may come to believe that one's conformity to existing norms is a good test of one's responsibility as a citizen. Extreme right-wing governments, for example – whatever they may call themselves – may encourage extreme conformity to a societal norm, which may or may not be for the common good.

A second variable in determining the extent to which creativity is domain-specific is knowledge. Typically, to think creatively in a domain, one has to know what is known in a domain to go beyond what is known. Someone who is knowledgeable is at an advantage to be creative in a domain. But the advantage is tempered by several factors.

First, some domains require very intensive knowledge, whereas other domains require more extensive knowledge. For example, to be creative today in neuroscience, one must be intensively knowledgeable about the workings of the brain and about the research that has been done to date on the brain. The research in this domain is expanding at a rapid rate, so one must constantly be working to keep up to date.

But in many domains, the most creative people are those who are broadly knowledgeable and whose expertise is not limited to one domain. For example, in psychology, many of the most creative scientists have been very broadly trained, often initially studying a discipline other than their primary one. For example, John Gabrieli, one of the most well-known of contemporary neuroscientists, majored in English as an undergraduate. The advantage that broadly trained people have is that they can bring ideas from one field into another. For example, Herbert Simon brought ideas from economics into psychology in his concept of satisficing. George Miller borrowed many of his ideas in psychology from linguistics. So being broadly as well as deeply educated enables one to enhance one's creative thinking, at the same time that it may mean that the individual gets a somewhat later start in his or her contributions to the field.

The situation becomes even more complicated, because expertise in a field can impair as well as facilitate creativity. One can become so used to seeing things in a certain way that one becomes less, not more creative with the development of expertise. So the acquisition of specialized knowledge does not necessarily facilitate creativity. It also can diminish it. Whether it enhances or diminishes it is largely a matter of attitude, as discussed below.

A third variable that affects the domain generality of creativity is the extent to which the environments in which one lives support creativity. An individual does not live in one environment, but rather, in a multitude of environments. For example, one's family may encourage creative thinking, but one's workplace may not, or vice versa. Certain religions are extremely intolerant of deviations from norms, and may even punish such deviations with death. So one might be allowed to be creative in one's work, but not one's religious beliefs, or vice versa, in the case that an organization for which one works insists on blind conformity to a set of norms. Someone may have creative attitudes and an extensive knowledge base, but not be allowed to use them in order to be creative.

In recent work, Sternberg and his colleagues showed that scientific reasoning in general, and scientific creativity in particular, represent a domain of cognitive functioning that is distinct from the domain represented by the content of standardized tests of abilities, such as the SAT and the ACT. These investigators asked college-aged subjects to think scientifically—for example, to generate hypotheses, generate experiments, or evaluate experiments. These are tasks represent the kinds of thinking in which scientific researchers engage on a day-to-day basis. Levels of performance on these scientific-reasoning tests emphasizing creativity consistently correlated with each other, but did not consistently correlate with scores on standardized tests used for college admissions (ACT, SAT). Indeed, some of the correlations with the standardized tests were negative.

Conclusion

Students of creativity generally agree that creativity is not a unitary phenomenon, but rather, a complex one involving distinct components. These components appear not to be strictly additive, but rather, interactive. Although there is some disagreement among theorists, there is general agreement that the components involve cognition, knowledge, personality, motivation, and environment, as well as perhaps other things.

Introduction

Composers – persons who write down music for later performance, especially in the Western classical tradition – are among the most revered and beloved of all creators. For experts and laypersons alike, classical figures like Johann Sebastian Bach, Wolfgang Amadeus Mozart, and Ludwig van Beethoven loom as iconic, paradigmatic creative personalities. Research on such individuals constitutes a significant line of scholarship within the study of creativity. Such inquiries include archival studies of deceased classical composers – their lives, careers, and first-person comments about their creativity – as well as observational, laboratory, and interview studies of contemporary composers. This entry summarizes extant findings on the creativity of composers and discusses their implications for conceptualizing the nature of creativity more broadly.

Composers: Scope and History

Musical creativity encompasses a wide range of activities. The topic of this entry – composers – refers specifically to a person writing, notating, or otherwise recording musical ideas in some permanent form for later performance. Composing should be distinguished from performance, where a musician interprets already-written notes by playing or singing them, and from improvisation, where a musician – sometimes with the aid of an initial melody or agreed-upon harmonic sequence – creates new music in a real-time performance. Certain musical traditions, like American jazz or Indian raga, blend the roles of composer, improviser, and performer, often situating musical activities within group collaboration. Nearly all classical composers in the mainline Western tradition have also been adept performers and improvisers; many have also been distinguished conductors, critics, theoreticians, or impresarios. However, the notion of the *composer*, as an individual who occupies a distinct role that is separable from other musical activities, remains the prototype of high-level musical creativity for many people, perhaps especially in the West.

The status of composers was not always so lofty. While archaeological evidence shows that music has been an important human activity for tens of thousands of years, a unique societal role for composers requires the development of some system of musical notation. Such traditions developed in ancient Greece and in the Gregorian chant of medieval Europe.

The phenomenon of composers as distinct creative personalities is more recent. Among the earliest composers whose names and music both survive are Léonin and Pérotin, who flourished about 800 years ago in France. For the next 600 or so years, composers remained reliant on official patronage by religious or civic officials and institutions in order to scrape together a living, and conditions for creation were far more restrictive than today. Most music was written to order for specific occasions, rather than being the expression of a creator's personal inspiration. Composition and performance practices and obligations were often heavily intertwined. Music publishing technology developed, but copyright enforcement was lax to non-existent. Stylistic conventions evolved, new instruments were invented, and composers pioneered new musical forms (including opera) and new musical styles. Throughout this time, despite the gradual maturation of the European musical tradition through the innovative genius of figures like Giovanni Palestrina, Claudio Monteverdi, Johann Sebastian Bach, Franz Joseph Haydn, and Wolfgang Amadeus Mozart, composers continued to be regarded mainly as hired craftsmen and entertainers, rather than autonomous creators.

Around the year 1800, Ludwig van Beethoven emerged as a pivotal figure in the history of European music composition. He was the first major composer to make a living without institutional patronage, instead earning money on the sale and performance of his music. Beethoven also pioneered a highly influential musical style, which developed the techniques of his predecessors into individually distinct works of greater scope, density, and expressive intensity than anything heard before. His reputation as an isolated, brooding, difficult individual, wholly dedicated to his personal creative activity, added to the Romantic veneer, establishing new expectations for what a composer should be. No longer mere craftsmen, composers became prototypes of the highest form of innovative creative genius, a conception that persisted among later composers – like Richard Wagner, Claude Debussy, Arnold Schoenberg, and Igor Stravinsky – within the Western tradition in the 19th and 20th centuries and up until the present.

Historiometric Studies of Composers

One benefit of the enhanced status of composers over the last two centuries has been an intense interest in preserving and cataloging their works – including, retrospectively, those of earlier musical giants. Indeed, composers are among the best-documented of all creators, in any domain. The complete works of most great composers (including sketches and fragments) have been compiled in comprehensive detail. In many cases, a work's date of composition can be reliably established, and measures of the impact of each work – like citations in music history books or counts of commercially available recordings – can also be easily obtained.

The method of using such a paper trail of archival evidence as the raw material for scientific studies of creativity is called historiometry, a powerful methodology pioneered by psychologist Dean Keith Simonton. Such research has several important benefits. One is high ecological validity, since it deals with *bona fide* great creators and real-world indices of musical success. Another is that historiometry lends itself to quantification (say, estimates of the amount of music produced in a particular year), which allows rigorous statistical testing of hypotheses about the nature of creativity – particularly about patterns of eminence and of creativity over the lifespan. (See Historiometry)

Overall Productivity and Eminence

One tenet of many perspectives on creativity (including Simonton's) is that a creator's ability to produce new works is a fair index of their creative potential and, all else being equal, their ultimate historical eminence. Historiometrically, then, one would expect exceptionally eminent creators to be among the most productive as well. Among composers, as in many other domains, this is the case. Indeed, among the most remarkable features of great composers' creativity was the astonishing ability of figures like Wolfgang Amadeus Mozart, Franz Schubert, and Georg Frideric Handel to compose world-class music in very short order, with major masterpieces sometimes only taking a few days or weeks, and to sustain this level of creative activity for decades. Positive correlations have often been made between a composer's productivity and eminence, as measured by counts of pages in music history books on which that composer was mentioned (Murray, 2003). Moreover, the distribution of eminence scores for composers echoes that of every other complex domain that has been studied: most creative musicians are clustered at relatively low levels of achievement, with a long upper tail culminating in the stratospheric eminence of the very, very greatest composers in history – by common consent, Beethoven, Mozart, Bach, and Wagner.

Lifespan Creativity Trajectories

Analyses of overall productivity and overall eminence, however informative, are still somewhat limited, in that they do not inform composers' longitudinal patterns of output – that is, how creativity varies as a function of age. This is an important and surprisingly complex question, since there are many ways of measuring variables like age and creative productivity. Composers do not all follow the same career path, and the markedly varied outputs of different composers means that great care must be taken when aggregating their data into statistical analyses.

Expertise and BVSR Models of Lifespan Creativity

Beyond such methodological issues, also at stake are theoretical perspectives on the nature of creativity itself. The two main views are Weisberg's (2006) expertise acquisition view of creativity, and Simonton's (2011) blind variation and selective retention (BVSR) view of creativity. The two theories make very different assumptions about the nature of creativity and posit different predictions about how creativity unfolds over the lifespan, with important implications for the extent to which creativity might be controlled or sustained.

The expertise acquisition view emphasizes the importance of a person accumulating a vast amount of domain-specific knowledge. A minimum of about 10,000 h of intensive immersion within the domain is required to enable high-level creativity. Deliberate practice involves great concentration and structuring specific training tasks to facilitate improvement in the skilled performance of some complex activity, like playing the piano. In acquiring such a domain-specific knowledge base, budding creators begin to put it

to use via the mostly rational goal-directed problem solving and decision-making processes that drive the creative process. The expertise view is thus optimistic about the likelihood of creators being able to control important aspects of the creative process. Thus, expert creators should be able to continue to improve longitudinally and to sustain their creativity indefinitely – though few details about how they might strategize to achieve this are typically articulated.

In contrast, [Simonton's \(2011\)](#) BVSR perspective emphasizes chance and serendipity in creativity. In this account, mental elements are continually combined below the threshold of consciousness as the raw material for creative ideation; the most promising combinations emerge into conscious awareness and are then actively developed into finished creative products. The classic BVSR model views the initial combination process as inherently blind; the processes of elaborating ideas into finished works and the social reception of those works are likewise regarded as too complex to be reliably guided. Thus, at no point is the creator in complete control of the creative process, and the optimal creative strategy is simply to produce a lot of work, hoping that some pieces will achieve recognition. In other words, quality emerges from quantity, in line with the results on overall productivity cited above. Counterintuitively, the BVSR view also predicts that the most prolific period of a creator's career should typically yield both their best work and the greatest amount of second-rate work. Compared to the expertise acquisition view, the BVSR view is more pessimistic about the prospects for systematically improving creativity with age. This is especially true if a creator is at the cutting edge of a domain, with few landmarks to guide their process or evaluation. However, the BVSR perspective also suggests that creativity might be sustained by simply maintaining high productivity, in line with its quantity-drives-quality dynamic.

Career Landmarks and Quantity Trajectories

Both the expertise acquisition and BVSR theories make plausible claims about the nature of creativity. These claims have been extensively tested, and data from the careers of classical composers have played an important role in this line of research. The most direct evidence comes from empirical studies in which creators' careers are quantified – for example, by career landmarks like the ages at which various composers began studying music, began composing, wrote their earliest acknowledged masterwork, wrote their best work, wrote their final masterwork, and stopped composing altogether. Some analyses of career landmarks support the expertise acquisition perspective, in that even musical prodigies require at least a decade of intensive musical study before producing original works of lasting value. However, expertise acquisition alone does not explain some other findings, which are probably more readily attributed to creative potential or talent. For instance, the *very* greatest composers begin studying and writing music earlier and their production of masterworks spans a far longer portion of their careers, compared to their less eminent counterparts ([Simonton, 1991](#)). (See Talent)

Such findings can be understood via a parsimonious mathematical model of the BVSR theory ([Simonton, 1997](#)), which yields the typical inverted, backwards J-shaped trajectory for quantity of creative output. Typically, a creator's productivity starts low, rapidly climbs, peaks around age 40, then gradually declines. Varying the parameters of the mathematical model changes the shape of the productivity trajectory. For example, greater creative potential increases overall productivity and broadens the age span encompassing the career landmarks described above, although with no change of predicted age for the creation of best work. All of these claims are consistent with empirical findings.

Quality Trajectories and Hit Ratios

Lifespan creativity can be operationalized in other ways as well. Rather than examining just a few career landmarks or assessing productivity by total output irrespective of quality, alternative measures take the differential quality of creative products into account – via recording counts, citations in music history books, or expert ratings. Studies along these lines ([Kozbelt, 2011](#); [Simonton, 2000](#)) often found a single-peaked age function for creative achievement, as with productivity. This suggests some benefit of expertise, since on average composers improved the quality of their creative work for long stretches of their careers.

Similar results have been found for another statistic for assessing composers' career trajectories: hit ratio, or the proportion of masterwork-level music to total music written in different time intervals in composers' careers. This measure assesses the ability of creators to learn to wisely invest their creative resources, arguably the key issue in sustaining creativity. In contrast to the expertise perspective, the BVSR view has explicitly posited an inability of creators to do so, and some earlier studies (like [Simonton, 1977](#)) found results along these lines, with no systematic change in hit ratio with age. However, later work suggests these efforts were marred by methodological and statistical limitations, as noted in the most extensive recent study of composers' longitudinal hit ratios ([Kozbelt, 2008a](#)). In that study, the complete works of 65 eminent composers were tabulated and weighted by performance time; each work's masterpiece status was operationalized by several measures. Works were assigned to five-year age intervals, synchronized across composers by age at first masterwork, and hit ratios were calculated for each interval for each composer. Results showed a single-peaked overall hit ratio trajectory, with a maximum around age 50, and with age accounting for more variability in hit ratio than in overall productivity. Reliable age effects held even during composers' mature periods and even when composers' greatest masterworks were removed from the dataset, inconsistent with the null relation between hit ratio and age posited by the BVSR perspective. Overall, great composers thus seem able to continue to sustain and improve the quality of their creative work for long stretches of their careers.

Variability in Career Trajectories

Just as important as the overall longitudinal trend is variability in creative styles and trajectories among individual composers. Some composers seem boundlessly productive; others are perfectionists who produce relatively little finished music. Some write music in many different musical forms; others specialize, writing mainly operas or songs. Some write highly accessible works in popular styles; others work in highly innovative ways, composing esoteric works that may push the boundaries of what even constitutes music in the first place. Some composers achieve fame early on; others work for most of their careers in relative obscurity. Some are prodigies or produce their best work at strikingly early ages; others take a long time to develop, only incrementally improving and composing their most highly regarded music in old age.

Making sense of such variability is a significant challenge for creativity researchers. Along these lines, Kozbelt's (2008a, 2011) large-scale archival studies examined the issue of variability in composers' careers and found that composers who wrote their single best works later in their careers showed stronger overall longitudinal increases in creativity. Thus, composers' greatest works are embedded in characteristic long-term career paths. Moreover, late-peaking composers showed *weaker* relations between average annual output and hit ratio across age intervals. This suggests that for late-peaking composers, quantity does not drive quality to the extent that it does for early-peaking composers. Late-peaking composers appear to have developed a kind of creative wisdom that allows them to invest their creative resources with greater perspicacity, in contrast to more hit-or-miss early-peaking composers (Kozbelt, 2008a).

Such striking individual differences in composers' careers have been interpreted via a framework proposed by economist David Galenson (2006), who proposed two main categories of creators: 'finders' and 'seekers.' Finders, or conceptual innovators, show great certainty during the creative process and prioritize originality and idea generation. They rebel against tradition and often change styles abruptly, and their reputations often rest on a small number of outstanding individual pieces, which they usually produce early in their careers. In contrast, seekers, or experimentalists, engage the creative process through trial and error and prioritize skill and the execution of ideas over their raw originality. Building on tradition, they develop slowly and surely, usually producing their best work late in their careers. Seekers' reputations tend to rest on an overall body of work of relatively consistent quality. Kozbelt (2008a, 2014) found that Galenson's model applied very well to classical composers, accounting for individual differences in career trajectories as well as compositional methods and concerns. Figures like Robert Schumann, Franz Liszt, Richard Strauss, and Igor Stravinsky were prototypical finders; those like Franz Joseph Haydn, Johannes Brahms, Giuseppe Verdi, and Béla Bartók were prototypical seekers. (See Longevity)

Differences among composers' career paths have also been explored in a study of so-called one-hit wonders in classical music – that is, composers whose reputations are due largely or exclusively to a single well-known composition (Kozbelt, 2008b). On average, one-hit wonders write their most acclaimed work at a younger age than do multi-hit composers, despite one-hit composers generally getting a later start in the domain. Not only did the two groups differ in age, but also in the kind of music they wrote. One-hit wonders' hits were typically songs or short instrumental pieces (genres where chance is more paramount), rather than large-scale works like symphonies. Indeed, few of the one-hit composers even attempted to write in such elite musical forms.

In sum, archival methods have illuminated many aspects of composers' lifespan creative output. On average, overall output, irrespective of quality, is given by an inverted, backwards J-shaped trajectory, as in many domains. Measures of work quality or hit ratio appear to show a similar trajectory, though with substantial individual differences. Some composers peak early, producing chancily innovative works; others pursue their craft and style more incrementally, producing a body of great work whose very best exemplars tend to be written late in their careers. Finally, it is worth noting that many of the basic findings on classical composers reviewed here have also been replicated on other samples, including Hollywood film composers and popular song writers.

Melodic Originality as an Index of Composers' Creativity

Beyond questions specifically about patterns of lifespan creative productivity and achievement, archival methods have informed other issues in the study of composers' creativity as well. In particular, one variable that has been subjected to decades of analysis is that of melodic originality (see Simonton, 1994). Originality in this context is defined statistically, as unusual sequences of notes. Given a large population of melodies, one can calculate the likelihood of particular notes in the musical scale being the first note in the melody, second note, and so on. Many melodies unfold very predictably, with certain transitions occurring frequently within the population. Other melodies are far more surprising, with unusual transitions occurring more often. Averaging over a measure of infrequency for each transition in a melody produces an overall sense of that melody's originality.

Quantitative measures of melodic originality can be statistically analyzed to examine many questions about musical creativity, since presumably the choice or construction of a melody represents an important decision-making aspect of musical composition. Indeed, a great melody can be the main driver of a work's popular or aesthetic appeal. Melodies are sometimes also seen as a window into the composers' state of mind. For instance, tortuously chromatic melodies are sometimes thought to be emblematic of a composer's mental distress at the time of composition.

Measures of melodic originality have been validated in several ways. For instance, research showed that originality is higher for melodies written in minor keys, compared to major keys – in line with the most exotic sound of minor-key music. Instrumental melodies are also higher in originality than vocal melodies – perhaps because of the inherent constraints in the human vocal apparatus compared to greater freedom on many instruments. More original melodies tend to be found in chamber or instrumental

works, where melody must carry more of the musical argument. This is especially true compared to theatrical works like operas and ballets, which tend to feature melodies lower in originality, perhaps because they contain many other performance features (scenery, narrative, and so on) that can contribute to a work's aesthetic impact. Melodic originality also correlated positively with ratings of compositions' aesthetic significance, a gauge of profundity and meaningfulness, and to correlate negatively with ratings of compositions' accessibility, essentially an 'easy-listening' measure.

Another question is how melodic originality changes over historical time. Stylistically, classical music has evolved through many styles: Renaissance, Baroque, Classical, Romantic, Impressionist, and Modernist are some of the most common labels. Within each major style, numerous sub-styles – due to geographic or temporal or individual differences – have also been identified. Melodic originality is one metric of how classical music has evolved. For instance, later styles tend to have more chromatic (off-key) notes than earlier styles. This reflects greater pressure on later composers to outdo their predecessors by producing more original and surprising musical themes. Empirical investigations of this issue, using a corpus of thousands of melodies, yielded findings in line with this intuitive trend. However, defining originality with respect to an overall population of melodies has its own methodological issues. For instance, highly productive composers with a recognizable style contribute more melodies to the overall repertoire, inherently making their melodies *less* original.

A related question concerns how melodic originality changes over the lifespans of composers. The research described earlier, on how creativity in general fluctuates over the lifespan, suggests that many composers may learn to become more creative over time. Some research on lifespan melodic originality is consistent with this, finding general increases in melodic originality with age (at least until composers' mid-fifties). However, other research, using somewhat different statistical methods, has failed to replicate these overall relations between age and melodic originality.

Many other aspects of composers' creativity – both external and internal – are apparent in studies of melodic originality. For example, on the external side, composers who were born and raised far from major centers of musical activity – where presumably pressure for novelty and innovation are lower – tend to show lower overall levels of melodic originality. Another external factor is that of warfare: works composed under wartime circumstances tend to show much higher variability in the originality of their constituent melodies than works composed during times of peace.

Internal or personal factors also appear to play a role in composers' melodic originality. For instance, a composer's overall level of productivity is inversely related to the melodic originality. That is, during periods of their careers when composers write the most music, the melodies in that music tend to be more pedestrian, suggesting a tradeoff between quality and quantity of output. Melodic originality also appears to intensify in periods when composers suffer from some critical physical ailment or high levels of mental stress. This finding is in line with the common belief that music represents a way for the composer to communicate emotionally with their audience.

A final phenomenon examined used measures of melodic originality (as well as aesthetic success) is the so-called swan-song phenomenon. Some research found that in the year or two preceding death, composers' works undergo a substantial transformation: melodic originality decreases, work length decreases, but the works themselves tend to be more popular and to garner more critical acclaim. This view of composers being able to concentrate their creative resources into a last testament of creativity is appealing, but as with some other findings on melodic originality, more recent research, using different statistical approaches, has questioned these earlier conclusions.

Other Historiometric Aspects of Composers' Creativity

Besides overall patterns of lifespan creative productivity and achievement and the multifarious studies using melodic originality as a variable, researchers pursued other lines of scholarly inquiry using archival measures. Two representative instances are discussed here.

One is related to some of the issues in lifespan creativity identified earlier – specifically, the extent to which creators can learn to reliably evaluate their own ideas and works, and to wisely invest their creative resources accordingly. Recall that the classic BVS perspective posited that doing so would be very difficult, but that subsequent evidence suggested that many composers do indeed continue to improve for much of their careers in work quality and in hit ratio. A classic example of this, much discussed in the creativity literature, is Beethoven. His famously effortful composition process involved making numerous sketches and drafts, with works evolving and sometimes changing radically in conception before taking their definitive form. In navigating and assessing this complex process, did Beethoven have a good sense of which works were likely to be seen as successful, or not? One case study (Kozbelt, 2007) thoroughly examined Beethoven's letters and contemporary accounts, to comprehensively catalog all instances where Beethoven rendered an explicit positive or negative verdict on any of his own compositions. The 70 works so identified were then assessed on posthumous measures of work quality or masterwork status. Results showed a strong positive association between Beethoven's own assessments and those of posterity, suggesting that Beethoven's sense of the differential quality of his work was well-calibrated. Interestingly, informal analyses of other composers' self-critical comments suggest that some composers (typically those who fall into Galenson's 'finder' category) are biased to regard most of their work in very positive terms, while others (typically those who fall into Galenson's 'seeker' category) may be biased toward harshly self-deprecatory comments about their own music (Kozbelt, 2012).

Another important issue in the study of composers' musical creativity, and one which has received lots of attention in the creativity literature more broadly, is the role of mental illness in creativity. Several notable composers – like Robert Schumann and Hugo

Wolf, who both died while institutionalized – appear to have had severe mental health problems. However, reliable data on the association between creativity and mental illness is difficult to obtain, especially for long-deceased creators, and this research area remains plagued with methodological and conceptual controversy. Such limitations have not held back some scholars from exploring this contentious area. For instance, in one recent archival study, [Simonton \(2014\)](#) examined the relation between alleged mental illness and creative eminence in several domains, including classical music. Different domains showed varied relations between the two constructs. Classical composers showed a slightly convex positive function of psychopathology on eminence, with peak average eminence associated with moderate levels of psychopathology. However, mental illness *per se* may be less directly important for creativity than the broader impact of diversifying experiences. As with many complex questions (including the classic nature vs. nurture issue), the relation between creativity and mental illness is a research area that is ripe for further exploration – through archival data as well as approaches that are grounded more in personality, developmental, social, and neurobiological aspects of psychology, as well as genetic studies.

Modern Composers at Work: Studies of the Creative Process

Beyond the use of archival data to explore questions like lifespan creativity among eminent but deceased composers, several other kinds of methodologies have allowed researchers to draw a rich picture of the composer at work ([Sloboda, 1985](#)). For instance, musicologists used composers' sketches and notebooks to understand their composition methods and creative processes. However interesting such inquiries may be, thoroughly understanding such sketches requires enormous attention and domain knowledge, as well as intensive interpretation, while typically yielding only provisional conclusions.

Beyond the evidence of their sketches, many composers also left first-person descriptions of their creative process. Some of these are quite famous, like Richard Wagner's dream-like account of hearing the low rumble of a stream, which served as the inspiration for the prelude to his opera *Das Rheingold*. However, as with sketches, such anecdotes require scholars to provide significant context and interpretation. Also, it is not always clear how trustworthy composers' claims about their creativity might be, particularly if they lack corroborating evidence. Some composers might make the creative process seem more Romantic and ineffable than it really was; others, more logical; others, more replete with difficulties. Moreover, cherry-picked anecdotes can be used to support any theoretical position ([Kozbelt, 2007](#)).

To minimize such problems, some researchers investigated the nature of composers' creative processes by more systematic interview and/or observational methods, sometimes supplemented with analyses of sketches and works-in-progress. In some observational studies, composers are asked to verbalize their thoughts while working. This can reveal much about a composer's concerns and goals. To cite just one example: [McAdams \(2004\)](#) conducted a case study of contemporary composer Roger Reynolds, using his notebooks, sketches, diagrams, recorded interviews, and the final score to document and understand the process by which a new work for piano, chamber orchestra, and computer-processed sound was created – in particular addressing how several significant compositional problems were solved.

Studies of the creative processes of contemporary composers have advanced numerous concepts relevant to understanding the creative process. These include the mental chunking of processes and strategies at both micro and macro levels, generative processes of problem proliferation and successive solution implementation, the deployment of synoptic planning versus heuristic ideation, generating rules in the course of music writing, cycle development and concern of coherence, and creative borrowing as crucial parts of creative cognition. While rooted in the study of composers, such theoretical concepts may also inform other domains and aspects of creative activity.

Moreover, beyond cognitive mechanisms and processes, self-regulation and self-monitoring processes also appear to be important for many aspects of complex problem solving, including music composition. Aspects of self-regulation appear to be vital for the development of high levels of expert performance, which in itself is a prerequisite for creative achievement. Both require high levels of motivation, and in the in the domain of music, substantial differences were found between beginners, novices, and experts in their knowledge and deployment of self-regulation strategies. As [Kozbelt's \(2007\)](#) case study of Beethoven's self-critical comments suggests, accurate self-monitoring and self-assessment processes may constitute an important – if still understudied – aspect of high-level creativity.

Conclusions and Implications

The study of classical composers represents one of the most enduring and informative aspects of research on Big-C creativity. Composers are perhaps the most intensively studied group of high-level creative personalities, and their well-documented lives and works are unusually amenable to statistical analysis and the testing of hypotheses about the nature of creativity. Archival research has been a particularly important facet of this line of inquiry. Researchers documented robust findings on lifespan creative output and achievement, the relation of output to eminence, and on quantifying trans-historical style changes in the domain.

Beyond such classic findings on composers as an aggregate, more recent research also often placed a greater emphasis on individuals. For instance, in the last couple decades, archival studies focused on understanding the substantial individual variability among elite creators. Some of this work highlights important theoretical points, such as the possibility that meaningful control and evaluation of the creative process might be more common than previous thought (at least from the classic BVSR perspective).

Recent research also emphasizes methodological points, such as the dangers of ignoring, downplaying, or averaging across creators of very different types, domains, or levels of productivity. Finally, archival research continues to play a vital role in studies of venerable themes in the study of creativity, like its relation to mental illness.

Beyond historiometric analyses of deceased composers, the study of contemporary composers – through interviews, think-aloud laboratory studies, and the examination of sketches and scores – represents another major inroad in understanding the process of musical composition. The advent of neuroimaging techniques, and their application to evermore complex and ecologically valid tasks, likewise promises to continue to advance knowledge of creativity among composers.

Through all these varied methods, the study of great composers has materially advanced knowledge of creativity. The conclusions from this line of scholarship have significant potential application to understanding creativity within many other domains and as a general phenomenon worthy of scientific study.

Introduction

This entry sketches a Confucian conception of creativity based on the teachings and example of Confucius as recorded in the *Analects* – a Chinese classical text that compiles the sayings and conduct of Confucius and his followers. Confucius or Kong Fuzi (c. 551–479 BCE) aspired to eliminate the political and social chaos of his time through his instruction and involvement in governance. In so doing, Confucius propounds insightful and unconventional ideas and practices that reveal his creativity, as this essay shall explain.

At the outset, it is helpful to briefly discuss East Asian understandings of creativity. Despite divergence of views on the definitions, contents, processes and outcomes of creativity, scholars general agree that creativity involves some form of newness or change (for helpful readings on the history of research on creativity, see [Albert and Runco, 1999](#)). East Asians, like their counterparts in Anglo-phone societies, associate creativity with attributes such as originality, imagination, intelligence, individualism and goodness (including both moral goodness and usefulness) ([Niu, 2012](#); [Niu and Sternberg, 2006](#)). But the precise formulations, parameters and expressions of creativity stem from and are shaped by local social, cultural, and historical contexts. Researchers have reported major differences between Western and Eastern conceptions of creativity. Creativity as manifested in incremental originality, progressive adaptation, alternation of existing schemes or practices over time, domain-specific development and a reinterpretation of tradition are more privileged in East Asia as compared to Western settings ([Niu and Sternberg, 2002](#)). East Asians are unlikely to look favorably on models and applications of creativity that call for a revolutionary break from the past, radical novelty and disruptive changes ([Kaufmann and Beghetto, 2009](#)). What is preferred instead are innovative ideas, mechanisms and systems that are premised on and extended from existing traditions and cultures ([Tan, 2016a, 2019](#)). East Asians also play up the ethical and communal dimensions of creativity by emphasizing moral goodness and societal contribution ([Rudowicz and Yue, 2000](#)). Self-cultivation is integral to creativity: individuals are exhorted to invest in self-transformation and perfection through internalizing and displaying personal and communal virtues ([Tu, 1985](#)).

This essay sheds further light on East Asian perspectives on creativity by focusing on a Confucian approach to and practice of creativity as found in the *Analects* (all the passages from the *Analects* were translated into English by the author). Confucius' conception of creativity is *in situ* (on site) that is contrasted with *ex nihilo* (out of nothing) ([Ames, 2011](#)). The former underlines situation where “the act of creating and self-creativity are inseparable” ([Ames, 2011](#), p. 254). *In situ* creativity, unlike *ex nihilo* creativity, does not foreground discrete agency, originality, novelty, retrospection and dependence on its origin as a source of value. Instead, *in situ* creativity is prospective by emphasizing the productivity and significance of constitutive relationships. In contrast to *ex nihilo* creativity that negates histories, processes, particularity, synthesis and the wholeness of experience, *in situ* creativity values the past, antecedents, contingencies, possibilities and harmonization. The rest of the entry shall expand on three salient features of Confucius' *in situ* creativity: normative tradition, context and human interdependence.

Confucius' *In Situ* Creativity

Normative Tradition

The first essential characteristic of Confucius' *in situ* creativity was his accent on realizing and perpetuating the normative tradition. Rather than ignoring or downplaying the past, Confucius averred that creativity should “keep alive the old in order to know the new” (*Analects* 2.11; all subsequent citations are from this text). Creativity is not *ex nihilo* but situated in concrete and localized histories, cultures and discourses. All modes of thinking, including creative engagement, need to be accompanied by the learning of one's culture ([Tan, 2015](#)). Confucius propagated the imperative to “learn culture broadly” (6.27); he shared that he “quietly stores up what is learnt and is insatiable in learning” (7.2, also see 7.17, 9.2). Commenting on his own mistake, he said: “I once went without food the whole day and without sleep the whole night by focusing on thinking; that was not beneficial and it is better to spend the time learning” (15.31). That Confucius did not support revolutionary changes and instead advocated evolutionary progress is evident in his assertion that he “transmits but does not make; trusts in and loves antiquity” (7.1).

The “antiquity” in question is the Zhou dynasty in ancient China that was judged by Confucius to possess “the highest excellence of all” (8.20, also see 17.5). Declaring that he “follows the Zhou dynasty” (3.14), Confucius regarded the Zhou tradition as worthy of emulation. But it should be noted that what Confucius valued is not the historical tradition that has been passed down through the generations but the normative tradition or *dao* (Way). Confucius encouraged all to “learn in order to reach that Way” (19.7) and “be firmly committed to love learning, hold fast to the good Way till death” (8.13). The Way is the Way of heaven that embodies “a vision of human excellence” (Cua, 1989) and “guiding discourse” for all (Hansen, 1989). The Way is preserved and manifested in various forms such as traditional texts, cultural resources and the exemplary attitudes and conduct of sage-kings (Tan, 2013).

It is important to note that the Zhou dynasty is lauded by Confucius not for simply receiving and transmitting the beliefs, norms and ways of life of previous dynasties; rather, it is exalted for resourcefully adapting and adding to historical precedents in accordance with *dao* (Way). Such evolutionary changes were noted by Confucius who stated: “The Zhou dynasty builds on the normative behaviors of the Yin dynasty, and the abolitions and additions (made by the Zhou dynasty) can be known” (2.23). In the spirit of creative modifications, historical traditions should not be accepted unconditionally but should instead be (re)interpreted and appropriated through the lens of the Way. That the Way can – and should – be extended through human efforts shows that it is not monolithic, complete, fossilized and static. As Confucius put it, “It is human beings who are able to broaden the Way, not the Way that broadens human beings” (15.29). To broaden the Way is to attain and expand on the vision of human excellence from one’s cultural tradition (Tan, 2017). Confucius demonstrated the extension of the Way in his advice to judiciously select the praiseworthy elements from the past: “Follow the calendar of the Xia dynasty, ride on the carriage of the Yin dynasty, wear the ceremonial cap of the Zhou dynasty, and as for music, play the *shao* and *wu*” (15.11).

Context

The second defining feature of Confucius’ *in situ* creativity was his attention to context that revolved around particularity, contingencies, processes and harmonization. To broaden the Way, according to Confucius, is to live a life that adheres to *li* (normative behaviors). Conforming to *li* entails “learning and practicing what one has learnt from time to time” (1.1) in particular situations. Underlining the all-encompassing nature of *li*, Confucius exhorted all: “Do not look unless it is in accordance with *li*; do not listen unless it is in accordance with *li*; do not speak unless it is in accordance with *li*; do not move unless it is in accordance with *li*” (12.1). *Li* is a personal, inspirational application of the normative tradition through desirable values, attitudes, dispositions and conduct (Tan, 2013). Examples of *li* listed in the *Analects* include mundane activities such as one’s posture (10.12; 10.10; 10.24), greeting someone (3.7), and interacting with others (12.2). *Li* demands that one responds autonomously, appropriately and flexibly in all problem-situations. Creativity is essential for the exercise of *li* as the former empowers one to make sense of, devise and alter existing ideas and practices to new and challenging circumstances.

The fact that Confucius’ approach to creativity was situational implies that it was highly personalized and essentially moral. The personalized aspect of creativity was testified to in Confucius’ description of a *junzi* (noble or exemplary person) as one who is “not inflexible” (15.37; also see 1.8) and like “a vessel” (2.12). During Confucius’ time, a “vessel” is a receptacle used for specific ceremonial occasions. Unlike a vessel that is restricted to a pre-determined function, a *junzi* (re)acts inventively to ever changing and unexpected situations. A *junzi*, “in one’s dealings in the world, is not for or against anything; such a person goes with what is appropriate” (4.10). Exercising one’s discernment, discretion, versatility and enterprise, such a person “selects what is good and follows it” (7.28). Confucius exhibited “creative personalization” (Ames and Rosemont, 1998) by responding in varied ways to different people. A classic passage in the *Analects* narrated his contradictory answers to two students who asked him the same question on whether they should act upon hearing something. To Zilu, Confucius stopped him from taking action on the basis that his father and elder brothers were still alive. But to Ranyou, Confucius encouraged him to act immediately. Confucius’ patently oppositional answers puzzled another student who sought clarification. Confucius replied: “Ranyou is diffident, and so I urged him on. But Zilu has the energy of two, and so I reined him in” (11.22). This episode illustrates Confucius’ creative responses by tailoring his teaching to suit the diverse personality traits and needs of the learners.

Besides being highly personalized, Confucius’ understanding of creativity was also fundamentally moral (Tan, 2016a,b). At the heart of *li* is *ren* (humanity or benevolence); Confucius pointed out that *ren* is simply to “return to *li*” (12.1). Associated with *ren* are virtues such as *xiao* (filial piety), *shu* (empathy and reciprocity), *zhi* (wisdom), *yi* (rightness or appropriateness), *yong* (courage), *he* (harmony) (12.1, 17.6). *Ren*-centered creativity directs human beings to gradually and prospectively broaden the Way that connects the past to the present and future. An example is Confucius’ judgments on the prevailing practices concerning ceremonial cap and prostration:

The Master said, “A ceremonial cap of linen is prescribed by *li*. Nowadays, a silk cap is used instead. This is frugal and I follow the majority on this. To prostrate oneself before ascending the steps to the hall is prescribed by *li*. Nowadays, one prostrates oneself only after ascending the hall; this is arrogant. Although this goes against the majority, I prostrate myself before ascending.” (9.3)

On both occasions, Confucius was guided by ethical considerations. In the first case, he supported the substitution of linen with silk for the ceremonial cap on the basis of frugality. In the second instance, he refused to go along with the common practice to prostrate only after entering the hall because doing so showed a lack of reverence. Confucius’ deliberations were based on moral principles that show the intrinsic *ren*-driven attribute of creativity. Relating context to broadening the Way, Hall and Ames

(1987) maintained: “Each important cultural figure in each historical period not only embodies *tao* [Way] in a particular manner appropriate to his unique circumstances, but also, with the energy of his own original contribution, is able to set the dynamics of *tao* on a novel course” (p. 232).

Human Interdependence

The final distinctive feature of Confucius’ *in situ* creativity was interdependence. Combining creating and self-creativity (Ames, 2011), Confucius stressed agendas and activities that promote not only one’s own interests and needs but also the productivity and significance of shared relationships. The interdependence of self and others was encapsulated in Confucius’ contention that “in helping oneself to take a stand, one helps others to take their stand; in desiring to reach a goal, one helps others to reach their goal” (6.30). In Confucian parlance, “taking a stand” denotes performing one’s social roles through displaying normative behaviors and corresponding values and attitudes (Tan, 2013). The process of taking a stand involves, among others, observing *li* (12.1, 12.2), loving learning (1.14, 8.13), learning extensively (9.2) and synthesizing the old and the new (1.1). “Helping oneself to take a stand”, it follows, is to cultivate oneself through self-directed learning, authentic moral motivation and personal articulation. Believing that all human beings “are similar in their nature but differ as a result of their practice” (17.2), Confucius posited that everyone can become a *junzi* as long as one puts in effort to improve oneself (14.42). Using himself as an example, Confucius shared that he was set on learning at the age of fifteen and was finally able to “follow my heart-mind’s desires without overstepping the line [*li*]” (2.4) when he was seventy years old.

But helping oneself to take a stand goes hand in hand with helping others to take their stand. As Hall and Ames (1998) put it, “creativity requires that each participant in a relationship be continually in the process of creating the other” (p. 273). A *junzi* is marked by one’s desire to “cultivate oneself in order to bring peace to the multitude” (14.42) and “love others” (12.22). There was therefore an inherent social component to Confucius’ notion of creativity. It is impossible, as envisioned by Confucius, for one to develop oneself in isolation without participation in and contributing to social relationships. According to Confucius, creating and self-creativity are facilitated by *zhengming* (rectification of names) where one lives up to one’s social role, be it as a ruler, minister, father or son (12.11). Pointing out that “when names are not correct, what is said will not be used effectively” (13.3), Confucius reminds us that one’s name conveys normative and communal implications and value. Creativity is relevant to *zhengming* since one cannot be a good ruler, minister, father or son by performing one’s role mechanically or thoughtlessly. Instead, what makes one a good ruler, minister, father or son in the eyes of others are conscious, purposeful and motivational attempts to meet the expectations that commensurate with one’s name in specific contexts.

Central to the affirmation and enhancement of shared relationships is the virtue of *he* (harmony or harmonization). Harmony is prized for “making the Way of the Former Kings beautiful, and was a guiding standard in all things great and small” (1.12). Harmony is attained when human beings not only enjoy inner peace but also co-exist with and build up one another in accordance with *li*. Confucius gave details to harmony in the following passage:

The Master said, “Little ones, why do none of you study the Songs? The Songs can give you inspiration, observation skill, ability to live with others, and means to express grievances. The Songs enable you to serve your father at home and your lord in public. You will learn broadly about the names of birds, beasts, plants and trees” (17.9).

Starting with oneself, studying poetry develops one’s imagination and moral cognizance through looking and listening (“inspiration”, “observation skills”, “learn broadly about the names of birds” etc.), speaking (“means to express grievances”), and moving (“ability to live with others”, “serving your father at home” etc.). The attainment of inner peace is complemented by external harmony where one lives amicably and collaboratively with other members of society (“ability to live with others” etc.) and nature (“learn broadly about the names of birds, beasts, plants and trees”). Anchored on harmony, one enriches and fortifies oneself through an ever-expanding circle of human relatedness (Tu, 1985). An analogy is four concentric circles, with moral self-cultivation in the innermost circle, followed by circles representing one’s home (parents and siblings), one’s community (one’s peers, juniors and elders) and finally the world (general society) (Tan, 2013). The interdependent aspect of Confucius’ creativity explains why he valued an attitude of open-mindedness, humility and mutual learning. He articulated, “When walking with two other persons, I am bound to find a teacher among them: I choose to follow the good person, and correct myself when I am with a person who is not good” (7.22).

Conclusion

This entry maintained that Confucius’ *in situ* creativity is not a break from the past but grounded in the vision of human excellence that originates from one’s culture. Rather than underscoring individual efforts and interests, the Confucian notion of creativity presented shines the spotlight on constitutive relationships and role ethics. As a “conservative innovator” (Tan, 2015), Confucius preserved and extended the normative tradition by creatively adapting it to episodic events and infusing it with moral and social significance. The continuation and furtherance of the Way is pivoted on an original and flexible appropriation of symbolic resources

for particular problem-situations. It is pertinent that Confucius ingeniously (re)defined well-known terms in ancient China such as *li* and *junzi* in his quest to bring to the fore the Way (Tan, 2017). He enlarged the meaning of *li* beyond the traditional meaning of ritual propriety to include all normative behaviors that are supported by corresponding values, attitudes and dispositions. In like fashion, he re-interprets the term *junzi* from the original meaning of an aristocrat to an educational ideal that is achievable by all. The Confucian conception of creativity as delineated in this entry is incongruent with perceptions of Confucianism and Confucian education that neglect, undermine and imperil the development of creativity. A dominant Confucian tradition in East Asia is one that brings to mind authoritarianism, unquestioned obedience, the maintenance of status quo, rote memorization, indoctrination and suppression of individuality (Kim, 2007). Offering an alternative reading of Confucianism, this entry has presented Confucius' *in situ* creativity – one that celebrates normative tradition, context and human interdependence.

Introduction

Over time, the field of creativity research has seen a gradual shift away from an almost exclusive emphasis on the creative person towards a more balanced inquiry that centers both on individual difference issues and questions about the nature of creative products and the conditions that facilitate the creation of those products. The consensual assessment technique (CAT) allows for the assessment of the relative creativity of products and is based on the assumption that a panel of independent raters, persons who have not had the opportunity to confer with one another and who have not been trained by the researcher, are best able to make such judgments. Over 40 years of research have clearly established that product creativity can be reliably and validly assessed based upon on the consensus of experts. Although creativity in a product may be difficult to characterize in terms of specific features, it is something that people can recognize and agree upon when they see it.

The CAT has been successfully used in hundreds of between-subjects designs focused on the question of whether some conditions are more conducive to creativity than others. The conditions experimentally compared have been both naturally occurring (as in field studies conducted in industrial/organizational studies) or artificially created and manipulated by an experimenter. Study participants are sometimes drawn from a single, underlying population or they might represent persons coming from a variety of different backgrounds, cultures, etc. Within-subjects designs can also incorporate the CAT to explore whether some conditions are especially conducive to or detrimental to creativity. In addition, the CAT can be used to assess the relative creativity of products produced by individuals who have submitted their work to professional competitions (e.g., graphic design or marketing) or to compare product ratings made by different groups of judges: experts vs. novices, supervisors vs. employees, teachers vs student, children vs. adults, judges in one culture vs. judges in another culture.

The Unique Assessment Concerns of Creativity Researchers

A variety of personality checklists have often been used to identify highly creative persons as well as personality traits or cognitive styles associated with creative performance. Other creativity indices have focused on behavioral factors. These behavioral assessments, such as the Torrance Test of Creative Thinking (TTCT; [Torrance, 1974](#)) have typically built on Guilford's theory of divergent thinking ([Guilford, 1976](#)) and elicit oral, written, and drawn (nonverbal) responses from participants.

But what does it mean when someone scores high (or low) on these creativity tests? Should high scorers be considered "creative persons?" Many creativity measures might accurately tap one or more creative abilities or predispositions, but it is most unlikely that a single test could be developed that would capture the full range of creativity components. Also troublesome is the fact that a variety of social and environmental factors have been found to influence test results. Study participants' scores can be improved simply by

telling them that creative responses will be valued, and many investigations have shown variability in creativity test scores under different testing conditions and time constraints.

Even if contextual and situational factors could be controlled for, the construct validity of many of these tests has also been seriously questioned, as has the convergent validity of different test procedures considered together. This validity issue is especially problematic given the fact that many of the leading creativity tests have been validated against one another. Moreover, some tests equate divergent thinking and even fluency (number of responses) with creativity; and other scoring procedures, while purported to be objective, are based upon the test constructor's own intuitive notion of what is creative.

Early Applications of Consensual Assessment

Mindful of these and other difficulties inherent in the creativity testing process, a growing number of researchers have become convinced that creativity judgments can ultimately only be subjective. Rather than attempting to objectify the creativity rating process, these investigators rely on the consensual assessment of persons or products. In fact, the subjective assessment process has a long history. As far back as 1870, researchers were relying on biographical dictionaries to select outstanding literary figures and scientists. Early research done by Cox (1926) drew a pool of geniuses for a personality study from Cattell's list of the 1000 most eminent individuals in history. More recently, Simonton developed a measure of creativity based on frequency of citation in histories, anthologies, and biographical dictionaries.

Other investigations have relied on the judgments of a select group of experts to assess the creativity of particular individuals. For example, an expert-nomination procedure was carried out by MacKinnon et al. for a series of studies in the 1960s at the Institute for Personality Assessment and Research in Berkeley, California (Mackinnon, 1964). Helson and Crutchfield gathered mathematicians' nominations for the most highly creative women in their field (1970); and Barron (1966) requested that three professors of English and one editor of a literary review suggest names of creative writers.

Shifting their focus away from the creativity of persons, some researchers have instead asked raters to make assessments of the creativity of particular *products*. In the majority of investigations of this type, the researcher has either presented judges with her own definition of creativity for them to apply or has trained them beforehand to agree with one another. While such methodologies may successfully avoid many of the problems inherent in paper-and-pencil creativity tests, the fact that judges have been carefully instructed in the rating process calls into question both the claim of judge-based subjectivity and the meaning of interjudge reliability. Rather than impose specific definitions of creativity or related dimensions, researchers would be better served if they allowed judges to make their own, independent product assessments. In this way, creativity assessments will more closely mirror real-world assessments.

Getzels and Csikszentmihalyi (1976) did just this when they requested that four different groups of judges (two expert and two nonexpert) use their own individual criteria when rating drawings on originality, craftsmanship, and overall aesthetic value. Soon thereafter, Sobel and Rothenberg also utilized this subjective assessment technique. Investigations such as these managed to overcome much of the criticism levied against the earliest applications of consensual assessment to product creativity, yet a variety of difficulties still remained. First, many of the procedures failed to differentiate between the creativity of products and other related constructs such as technical correctness or aesthetic appeal. Further, most of these early researchers did not clearly state an operational definition of creativity, even when they had trained their judges to recognize specific creativity criteria in products. Nearly all contemporary definitions of creativity are conceptual rather than operational. They were never intended to be translated into actual assessment criteria.

Systematizing the Consensual Assessment Technique in Creativity Research

The consensual assessment of creativity was first formalized and systematized by Amabile's work in the social psychology of creativity, beginning in the late 1970s. When this program of investigation was started, existing creativity measurement tools, including available subjective assessment methodologies, could not meet the unique research requirements of investigators interested in the social psychology of creativity. The majority of available assessment techniques viewed creativity as an enduring personality trait. Most paper-and-pencil measures had been specifically constructed to maximize individual differences. Even existing subjective assessment methods relied on products or entire bodies of work that depended heavily on an individual's level of expertise. Prior methods had been constructed to do exactly what social psychologists interested in the impact of the social environment on behavior are trying to avoid.

In social psychological studies, individual difference effects must be minimized. Creative task performance must not depend heavily on participants' specialized skills. Prior to Amabile's work, the literature had not identified a methodology that could de-emphasize individual differences between subjects. In addition, researchers had not agreed upon and consistently employed an operational definition of creativity. Amabile's first step was to adopt two complementary definitions of creativity: an underlying conceptual definition to use in building a theoretical formulation of the creative process and an operational definition to apply in empirical research (Amabile, 1982).

Amabile's conceptual definition of creativity rests on the premise that a product or idea is creative to the extent that it is a novel and appropriate response to a heuristic task. This definition is similar to a number of others that came before it. Despite the implicit emphasis on the person in creativity assessment, most explicit definitions have used the creative product as the distinguishing sign of creativity. Indeed, the criteria of product novelty and appropriateness have long been seen as the hallmarks of creativity by a number of theorists.

The CAT is grounded in the original operational definition that Amabile developed: a product or response is creative to the extent that appropriate observers agree it is creative. Appropriate observers are those familiar with the domain in which the product was created or the response articulated. Importantly, this consensual definition is based on the creative product rather than the creative process. In fact, the majority of creativity assessment techniques require that study participants produce something – a list of ideas, a series of pictures, or the like. What sets this methodology apart from the rest is that, rather than responding to a series of pre-determined items or questions, study participants produce an actual product such as a poem, a collage, or a story. Perhaps the most important feature of this consensual definition is its reliance on subjective criteria. In this way, it overcomes the difficulty of attempting to specify ‘ultimate’ objective criteria for identifying products as creative. Indeed, it may be impossible to articulate such ultimate criteria. Judgments of creativity are necessarily subjective, relative and bounded by time and place. Creativity should not be seen as residing inside the artist or scientist or with judges representing a particular field of expertise. Nor does creativity reside in a particular culture or time period. Creativity is neither universal nor stagnant and must be seen as the result of a complex interaction between the three components of creator, domain, and field.

Amabile et al. have attempted to capture the essential characteristics of the conceptual and operational definitions of creativity in the CAT as used in experimental studies of creativity. First, study participants are presented with tasks that leave room for considerable flexibility and novelty of response (open-ended, heuristic tasks). Second, these are tasks for which the range of appropriate responses has been clearly identified in study participants’ instructions. Finally, in employing the CAT, researchers do not impose on raters their own specific views of what is creative or allow raters to influence each other; rather, raters work independently and are guided by their individual subjective conceptions about creativity.

Refining the CAT

The CAT rests on two important assumptions. First is the assumption that it is possible to obtain reliable judgments of product creativity, given an appropriate group of judges. In other words, although creativity in a product may be difficult to characterize in terms of specific features, it is something that people can recognize when they see it. Furthermore, people familiar with such products can agree with one another on this perception. A second assumption is that there are degrees of creativity such that observers can say, at an acceptable level of agreement, that some products are more or less creative than others.

Procedural Requirements

When utilizing the CAT, a number of requirements must be met. First, judges should all have had some experience (and roughly equivalent experience) with the domain in question. When Amabile et al. were first developing the CAT, they relied on the notion of ‘expert’ to describe an appropriate body of raters. Over the years, this view has come to be tempered. Basically, the method requires that all those rating products be familiar enough with the domain to have developed, over a period of time, some implicit criteria for creativity, technical goodness, and so on. For example, when asked to rate the creativity of paper collages, both children and adults from a variety of backgrounds have produced highly reliable assessments. When dealing with a more specialized and esoteric field, such as physics or computer programming, however, the range of ‘experts’ would certainly have to be considerably narrower. In either case, it is the judges’ familiarity with the domain that is important, not the fact that they, themselves, may have produced work rated as highly creative.

A second requirement is that the judges must make their assessments independently. They are not trained by the experimenter to agree with one another; are given no specific criteria for judging creativity; and are not allowed to confer in their assessments.

Third, judges should be instructed to rate the products relative to one another, rather than against some absolute standards they might hold. This is important because, for most studies, the levels of creativity produced by “ordinary” study participants will be very low in comparison with the greatest works ever produced in that domain.

Fourth, each judge should view the products in a different random order so as to avoid methodological artifacts.

Finally, if this technique is to be used to evaluate performance on a task to which it has not been applied in the past, judges should be asked to rate the products on other dimensions in addition to creativity. Minimally, they should make ratings of technical aspects of the work, and if appropriate, its aesthetic appeal as well. These additional assessments make it possible to examine the degree of relatedness or independence of these dimensions in subjective judgments of the products in question.

Once the judgments are obtained, ratings on each dimension should be analyzed for interjudge reliability. In addition, if several subjective dimensions of judgment have been obtained, these should be entered into a factor analysis to determine the degree of independence (discriminant validity) between creativity and the other dimensions investigated. Finally, if the products lend themselves to a straightforward identification of specific objective features, these features may be assessed and correlated with creativity judgments. Prior studies have identified some physical features of collages and some verbal features of stories that correlate with creativity judgments.

Reliability

Given the consensual definition of creativity, the most important criterion for the results of this assessment procedure is that the product ratings be reliable. In order to compute reliability, Amabile originally utilized the Spearman–Brown prediction formula

that is based on the number of judges (n) and the mean interjudge correlation (r). Because this technique yields results highly similar to both Cronbach's coefficient alpha and Intraclass Correlation (ICC), in recent years most researchers employing the CAT have relied on either Cronbach's alpha or ICC as their measure of interrater agreement. In fact, the Average Measures Consistency Formulation for ICC, where the same group of raters rate all the products in question, yields exactly the same value as does Chronbach's. In most instances, a reliability figure of 0.70 or higher can be considered evidence of an acceptable level of agreement between judges. Once such a level is reached, it is then appropriate to compute a sum (or an average) across all ratings given each product. These sums (or averages) then constitute the unit of analysis for further computations.

By definition, interjudge reliability in this method is equivalent to construct validity: if appropriate judges independently agree that a given product is highly creative, then it can and must be accepted as such. In addition, it should be possible to separate subjective judgments of product creativity from judgments of technical goodness and aesthetic appeal. Within some domains, it may be difficult to obtain ratings of product creativity that are not highly positively correlated with judges' assessments of product technical goodness or aesthetic appeal. Yet it is essential to demonstrate that it is at least possible to separate these dimensions, otherwise the discriminant validity of the measure would be in doubt. In other words, judges might be rating a product as 'creative' merely because they like it or believe that it is technically well-done.

Supporting Data

In the program of research carried out by Amabile et al. over the last 40 years, numerous studies have demonstrated that the CAT does, in fact, yield reliable measurements appropriate for social psychological studies of creativity. In studies targeting the performance of highly trained and experienced individuals, professionals and/or graduate students often serve as the "expert" judges. But in investigations focused on the creativity of students or enlisting a cross-section of untrained adults, classroom teachers or college students have also been recruited. Across domains, ten or so judges have typically been employed. Virtually without exception, raters have yielded highly reliable assessments of creativity.

Equally important as interrater reliability is the requirement that judges' assessments of certain additional product dimensions do not correlate highly with their ratings of creativity. Here too the results have been encouraging. In keeping with most theorists' conceptions of creativity, ratings of novelty and originality have typically been highly related to ratings of creativity, while ratings of various aspects of product technical goodness have not usually been significantly correlated with creativity assessments.

The most widely used measure of creativity employed in conjunction with the CAT asks study participants to create a paper collage. Amabile et al. have also incorporated a wide variety of other creativity tasks include the completion of five-line American haiku poems or the construction of free-form poems, the writing of essays and descriptive paragraphs, the construction of captions for cartoons, and telling a story to accompany an open-ended picture book without words. Each of these verbal tasks has also yielded highly reliable creativity assessments. Whether they are poets rating haikus, elementary school teachers rating children's stories or graduate students rating cartoon captions, judges show consistently high interrater agreement.

In addition to measuring artistic and verbal performance, Amabile et al. have also employed some creative problem-solving tasks. One assessment procedure calls for the construction of a geometric design on a computer screen. Another activity requires that young subjects fill in the outline of a geometric shape with colored pieces of felt. Problem-solving tasks appropriate for adults include the construction of computer programs, the building of structures from ordinary materials, and the generation of survival ideas, ideas for dealing with a variety of social situations, and ideas for high-tech products and business solutions. Although none of these techniques has been tested to the same extent as the collage-making or many of the earlier verbal creativity tasks, it is encouraging that judges have rated products produced by children and adults with high levels of reliability.

Recent work by Hennessey et al. investigated whether the CAT would also produce valid and reliable creativity ratings in non-Western cultural settings. Specifically, one series of five studies recruited school teachers from the United States, Saudi Arabia, China, Turkey, and South Korea to assess collages and stories created by children living in their local area. All children had been randomly assigned to expected reward or no-reward (control) conditions and were given identical task instructions and materials with which to work. Results confirmed that across all five cultural contexts, ratings of product creativity showed high levels of interjudge agreement. This suggests that the CAT is especially useful for cross-cultural investigations. Rather than impose a measure and scoring criteria originally developed for use in the West, the CAT allows for the subjective assessment of products by judges who come from the same cultural context as the study participants who produced the products (see [Hennessey et al. \(2008\)](#)).

Clearly, the CAT has wide-range application. It has been successfully employed with both child and adult participants and allows for the assessment of creativity in a number of different domains. Over the years, participant populations have been expanded beyond the original pool of undergraduates and elementary school children, demonstrating that the creativity of professional artists, professional art students, computer programming students, student poets, and employees of high-tech or graphic design companies can also be reliably assessed.

Taking a Closer Look

The CAT has consistently been shown to yield reliable measures of product creativity in a variety of contexts, but what is it exactly that judges are doing when they set out to make their ratings? Are they assessing only the completed product or are they also making assumptions about the process that went into producing that product? Can judges be expected to reliably assess features of the

creative process? Hennessey (1994) conducted a series of four studies with these questions in mind. Reliability was high and raters who had been asked to make assessments of process had no more difficulty than did raters assessing finished products. A strong and positive relation was also found between ratings of product creativity and ratings of the creativity of the processes that went into completing those finished products. And similar strong and positive correlations were found between ratings of the technical goodness of finished products and ratings of the technical goodness of the processes that lead to the completion of those products.

Another question: when asked to assess product creativity, are raters considering only the final product? Or do they also take into account other factors – factors such as information about the circumstances under which a product was produced or the characteristics of the creator? In investigations employing the CAT, judges are typically given very little information about the persons who have made the products they are to rate. Implicit in this procedure is the assumption that creativity is a unitary construct independent of factors such as background or experience of the creator.

The last of Hennessey's four investigations was intended as a preliminary exploration of the impact of artist age information on judges' creativity assessments. One group of undergraduates judged collages made by children and adults after receiving accurate information about the age of the artists. A second group rated the same collages after receiving false, reversed information as to the age of the artists. Finally, a third group of undergraduates made their ratings without being given any information as to the age of the artists. Reliabilities were highly acceptable for all three of the judgment conditions, and age information was found to have a significant effect. The highest creativity ratings were given to adults' collages that had been falsely labeled as children's products. The lowest creativity ratings were given by judges who had received no age information to collages that had been produced by children. Overall, it was found that those raters receiving age information about the artists, whether accurate or reversed, gave products higher ratings of creativity than did raters for whom no age information was available. Within age information groups, no significant differences emerged between judges' creativity ratings of children's and adults' collages.

Some of the judges polled reported that they had considered artists' ages when making their product assessments. Some other respondents mentioned "fighting" against the tendency to take artist age into consideration. Contrary to expectation, it was the mere availability of age information and not the specific adult or child label that affected raters' judgments. Whether raters were given an accurate or a reversed age label, they judged children's collages to be higher in creativity than did raters given no age information. This finding suggests that creativity theorists and other researchers wishing to employ the CAT must be certain to note whether age information has been made available, either purposefully or unintentionally, to judges. Similarly, careful assessments should be conducted to determine whether raters have made any age inferences on their own.

Does knowing a subject's identity inject bias into judges' creativity ratings? This question is particularly pertinent to field studies of creativity within the realm of organizational behavior, as researchers frequently elicit supervisory ratings of subordinates' creative behavior. This procedure necessitates that supervisors know the identity of the individuals who have produced the products or generated the ideas they are rating. While these studies typically control for workers' gender, age, organizational tenure, and other demographic variables that could impact creativity ratings, research has yet to determine the extent to which supervisors' attitudes, affective states or biases might impact their ratings in significant ways. This issue is of particular concern because most organizational studies rely on the ratings of only a single supervisor, violating a central tenet of the CAT. However, a study by Baer and Oldham (2006) did find that independent ratings by two supervisors correlated highly. Of course, it is possible that both supervisors were subject to the same biasing forces. Thus, ratings of an individual's work by people who know that individual must always be regarded with caution.

Another related issue is whether individuals can make reliable ratings of the creativity of their own work. Researchers have typically found moderate correlations between creativity self-assessments and mean ratings made by others, although self-ratings often show a positivity bias. For example, in a study by Moneta et al. (2010), workers' monthly self-assessments of their creative contributions to a project correlated moderately and significantly with independent ratings made by coworkers and supervisors. However, the mean self-ratings were higher than either the mean coworker ratings or mean supervisory ratings. Other researchers have found moderate correlations between self-ratings and peer-ratings. Indeed, a meta-analysis conducted by Heidemeier and Moser (2009) yielded an overall correlation of 0.22 between self and supervisory performance ratings. In sum, the literature suggests that self-ratings of creativity do relate to ratings made by external observers, but may be biased toward positivity.

A variety of papers have carefully explored these and other issues concerning the question of who should be considered an appropriate judge. In one study, parents and teachers were found to be equally accurate at recognizing the creativity of children's ideas. But other investigators found that young children's judgments about art were considerably different from those offered by older children. Runco et al. asked college students to each produce three three-dimensional artworks that were then rated by the students themselves, a group of their peers, and three professional artists. Analyses revealed that the student participants saw significant differences in the creativity of their own three art projects. Similar differences also were reflected in the peer ratings of the artwork. The assessments made by the professional artists, however, failed to reflect significant differences in creativity between products. Thus, vast differences in level of expertise between study participants and judges may influence creativity judgments.

Dollinger and Shafran (2005) reopened the question of whether nonexpert judges might reliably rate the creativity of drawings made by a sample of nonprofessional artists. In an interesting modification of the CAT, Dollinger and Shafran calibrated nonexpert judges' artistic creativity ratings by exposing them to 16 prototype drawings and corresponding ratings made by expert judges in a prior experiment. Subsequent to the calibration, the mean correlation between expert and nonexpert ratings for a second set of products was 0.91.

Taken together, these results suggest that some clarification or modifications be made to the CAT specification about what qualifies as an appropriate level of judge expertise. When rating products produced by either nonprofessional or professional

individuals, appropriate judges should be defined as persons whose expertise matches or exceeds the expertise of those individuals who created the products. In the case of products produced by nonprofessionals, if researchers desire nonexpert judges' ratings to correspond to ratings made by expert judges, researchers may use a calibration technique. Finally, if creativity assessment procedures require raters to have familiarity with the entire body of a given person's work – as is often the case in field research – the most appropriate judges will be those with the greatest knowledge of the individual's performance and output. Importantly, as cautioned earlier, future research in this area should consider the extent to which knowledge about a creator's identity might bias the validity of such ratings.

Recent Developments

Over the years, the CAT methodology has been extended to a variety of tasks in a variety of domains, and the diversity of participant populations and rater populations being studied is also constantly growing. Perhaps the most prolific expansion of the CAT in recent decades has occurred in the organizational domain. In field studies designed to investigate the creative performance of professionals, supervisors and/or coworkers are frequently called upon to serve as raters. As noted earlier, the majority of organizational creativity studies rely on the ratings of a single supervisor per study participant. This dependence on supervisor ratings draws on a decades-long tradition in the organizational literature of using such assessments to obtain quantitative measures of an employee's performance. Although the traditional CAT involves multiple judges rating the creativity of products using a single-item scale ("creativity"), the organizational domain has adapted the CAT to involve a single supervisor who rates several employees on a multi-item scale (e.g., "Searches out new technologies, processes, techniques, and/or product ideas"; "Generates creative ideas").

Recent advancements in the organizational behavior literature call into question the validity of supervisory creativity assessments. Mueller et al. (2018) showed that employees in a gate-keeping role, a role with responsibility for determining which ideas should be retained within a community, tended to rate the same idea as less creative if it had low (relative to high) social approval (e.g., Facebook likes, investor interest). Critically, those who were not in a gate-keeping role did not view social approval cues as relevant to creativity assessments. Further, social approval cues are negative and unreliable indicators of idea novelty and usefulness respectively. As supervisors often serve as gate-keepers of their subordinates' creative ideas, those in a supervisory role may exhibit a bias against creativity and so rate employees as having *lower* creativity if they generate highly creative ideas that lack social approval.

To overcome the limitations of using supervisor ratings to assess employee creativity, some organizational research has employed peer ratings of creativity – requiring every member of a team to independently rate the performance of every other member. This method appears particularly promising, as it allows researchers to assess inter-judge reliability. Yet other work in the organizational domain adheres more closely to the original CAT methodology by employing a set of independent judges to rate a specific idea (or set of ideas) developed by an employee. This practice allows for the calculation of inter-rater reliability and also diminishes the likelihood that the ratings merely reflect personal characteristics of the employee in question (e.g., age).

One additional arena of organizational creativity research that now frequently employs the CAT is the research on group creativity. Since the 1999 publication of the initial version of this encyclopedia, the investigation of group creativity has blossomed into a distinct, multifaceted, and highly prolific field of inquiry. Early brainstorming studies in the laboratory typically employed the CAT, requiring three or more expert raters to judge the originality of each idea produced by a group. The developing body of group creativity field research – like field research on individual-level creativity – has measured creativity in a variety of ways. Some field studies have employed a single rater to assess a specific product. At other times, group creativity research has employed multiple raters assessing either a single group product or the holistic creativity of a group. This CAT protocol allows for the calculation of reliability estimates, and is thus preferable to employing single judges.

Conclusions

Clearly, the CAT has been a great boon to many creativity researchers. It has broad application, is founded on a clear operational definition, and can be adapted to suit a wide variety of research situations. Moreover, with its similarity to real-world creativity judgments, the CAT enjoys a high degree of ecological validity. Despite these advantages, the CAT should not be considered an ultimate and universally useful means of creativity assessment. Indeed, this assessment methodology has some specific limitations. If time concerns are paramount, this approach is decidedly impractical. Choosing an appropriate task as well as an appropriate body of judges can be extremely time-consuming, as can the assessment of products and the necessary statistical data analyses. However, a number of creativity researchers continue to believe that the benefits of the CAT outweigh its costs; and recently, Kaufman et al. successfully experimented with a modified CAT technique that reduced time demands yet still yielded reliable assessments.

Perhaps the greatest strength of the CAT rests in the flexibility it affords to creativity researchers. First, the CAT can be used to obtain reliable assessments of the relative creativity (technical goodness, aesthetic appeal, etc.) of products made by a variety of individuals. Second, the CAT can be expanded to new participant populations, new performance domains, and new tasks that are quite different from those originally envisioned. In mimicking the way in which creativity is judged every day in the arts, the sciences, and the professions, the CAT helps bring creativity from the realm of the mysterious and the mystical, into the realm of the under-stood and the accessible.

Glossary

Contrarianism Intentionally doing what other people are not doing. The term was adapted from economics and has become recognized as a useful way to describe a popular tactic for insuring originality in many creative endeavors, even outside of economics.

Creativity Original and useful or effective behavior, solutions, or insights. The usefulness criterion implies that contrarianism is not sufficient for creativity; contrarianism only guarantees originality.

Dark side of creativity Original solutions and inventions used in immoral or unethical ways.

Discretion Discretion is the better part of valor—and the same holds true for creativity. Many decisions are involved with the expression of creativity so the creator is exercising discretion about what problems to solve, how original to be, and so on.

Misplaced investments Occurs when a contrarian tactic is used, but the person is not investing enough time and energy into the topic or problem itself. Time invested into being different is often time away from the focused work and persistence that is necessary for creative breakthroughs.

Oppositional thinking A proclivity towards unconventional cognition. It leads persons to do what others are not, but it is not a conscious decision and is therefore not strategic nor related to intentional creativity.

Postconventional contrarianism The recognition of rules and conventions, but maintaining the tendency to make decisions for one's self. It may involve exercising discretion before acting in a contrarian fashion. It may also be viewed as discretionary originality.

Introduction

Mickey Mouse was created by Walt Disney in the late 1920s. Mickey was a result of collaboration; Disney worked with his brother Roy and Ub Iwerks. Walt could no longer use his 'star performer,' Oswald the Lucky Rabbit, because his previous distributor held the rights. Disney needed a new star, and Mickey was conceived.

Why a mouse? As a matter of fact Walt wanted a cat. He discussed this with Roy and Ub, and they decided on a mouse. That decision was implicitly contrarian because Disney and his collaborators wanted to do what no one else was doing. The character Krazy Kat was already widely known and a second feline would be unoriginal. For that reason Walt and his collaborators decided on a mouse – to be different and unique.

Interestingly, the original suggestion was to call the new character 'Mortimer,' but Walt's wife Lily decided that "Mickey" was more appropriate. The discussion between Walt and Lily, summarized in *Walt Disney: An American Original* (Thomas, 1994), can be described in terms of group dynamics and strategies, Walt being very contrarian, and Lily making sure that the new mouse would have a name which would sound right to the general public. "Mickey Mouse" has a nice ring to it; and like other creative names, labels, and titles, it is fitting in some aesthetic sense. This is true of all creative insights and ideas, not just names, labels, and titles. Creative work is original, but it is more than just original. It is original and fitting. Sometimes the latter is a matter of aesthetic fit. Originality and fit (or effectiveness) are the two requirements of the standard definition of creativity.

Rationale for Contrarianism

There is quite a bit of detail about contrarianism in the economic and investment theories of creativity (Rubenson, 1991; Rubenson & Runco, 1992, 1995; Runco, 1991; Sternberg & Lubart, 1991). The rationale for contrarianism is as follows: Originality is a critical

aspect of creativity, and contrarianism has a high probability of leading to an original idea or behavior. It can be very practical because people can mindfully consider what others are doing and then do something different and original. If you just ask them to 'be original,' they may have some difficulty. There is often no clear-cut criterion with which they can actually judge their originality. But if you tell them to 'do what others are not doing,' they have something concrete to think about and to use in their efforts.

It is easy to be impressed by the contrarian tactic and see its value. There are several reasons. First, as just noted, it is operational and practical. It gives individuals something they can use when judging their ideas or behavior. Second, novel behaviors and actions are salient. For this reason the results of the contrarian effort are obvious. They often capture attention and may thus be rewarding. Third, it is an easy tactic to explain to others. Teachers, for example, can easily describe this tactic to their charges. A number of empirical projects have demonstrated how easily original thinking can be enhanced with contrarianism and other simple tactics.

Many biographies, autobiographies, and case studies mention contrarianism and tie it to creativity. The next section reviews example cases. The pros and cons of the contrarian tactics will then be discussed, as will limitations of case studies. As is true of all cases, they are merely illustrations, not evidence.

Individuals Who Have Used Contrarian Strategies

Many famous creative persons have used a contrarian tactic, in addition to Walt Disney. Gandhi was a contrarian, especially in his methods of passive resistance. These were fitting and original, given his beliefs and objectives. He found a way to both resist (which is in itself contrarian, at least *vis-à-vis* the British) and yet remain a passivist. Gandhi's passive resistance is paradoxical, being both resistance and passive, but this is true of many creative things. Passive resistance was paradoxical, contrarian, creative, and effective.

James Watson, who shared the Nobel Prize for his work on the structure of DNA, was contrarian as well. He collaborated with Francis Crick, and their competition with Linus Pauling was fierce (Watson, 1968). Sometimes competition requires contrarianism in that you do not want others to do what you are doing – or at least not until you have finished or established yourself.

In the medical research field Henry Heimlich (who developed the Heimlich maneuver) was long known as a maverick and nonconformist. Most recently he proposed curing patients with AIDS by giving them malaria. The *Los Angeles Times* claimed that "this is not the first time the 74-year-old Heimlich's headstrong approach to medicine has shocked, even outraged the Establishment." Heimlich was quoted as saying, "I don't do ordinary things. I don't follow all the rules if there's a better, faster way to do it" (Oct. 30, 1994: A30).

The *Los Angeles Times* also published an article, "Renegades Reinvent the Bicycle." Apparently the mountain bike – a modification of what *Britannica* called "the most efficient means yet devised to convert human energy into propulsion" – "came out of nowhere, a product of counterculture – invented by hippies, no less, a ragtag of pot-smokers and Haight-Ashbury drifters who barely got through high school." Note the term *counterculture*. This is one way of describing a group of contrarians.

A final example from the *Los Angeles Times* is Rock 'n' Roll. In a 1998 *Times* book review rock is called "a disagreement with established power – a refutation of authority's influence" (4/15/98, p. E6). Not that rock 'n' roll is the only rebellious kind of music. Duke Ellington was, for instance, quite the contrarian. Arnold Ludwig, author of *The Price of Greatness*, explained how "Knowingly or not, Ellington exploited traditional musical rules as inspiration for his jazz. If he learned that he was not supposed to use parallel fifths, he immediately would find a way to do so; if told that major sevenths must always rise, he would write a tune in which the line descended from the major seventh; and if the tritone was forbidden, he would find the earliest opportunity to use it and, to emphasize the point, would let it stand alone and exposed" (pp. 7–8).

The comment, "knowingly or not" is critical because by definition tactics and strategies are intentional. Unintentional contrarianism may best be viewed as *oppositional thinking*, which Ludwig (1995) defined as "the almost automatic tendency to adopt a contrary or opposite response" (pp. 7–8). Both contrarianism and oppositional thinking focus on what others are not doing, but the former is intentional, and thus tied to discretion, while the latter is unintentional and thus less likely to benefit creativity. Discretion will be discussed further below. But first several other examples of contrarianism should be mentioned.

Ludwig also described the work of Sigmund Freud. Certainly Freud's work was original, and yet it fit with his observations and with certain lines of medical theory. Freud was oppositional, and perhaps contrarian, in his efforts to do original work and in his nonconformity.

In the arts, Picasso described cubism as follows: "We were trying to move in a direction opposite to Impressionism." This is pure contrarianism, especially in its direction – namely, opposite to Impressionism. It is not just a reaction to others, and not just different, but *opposite*. In her chapter in the *Creativity Research Handbook* Stephanie Dudek argued that the Dadaists and Surrealists were "particularly determined to burn all bridges behind them." In this light, contrarianism breaks with tradition. That implies that *avant-garde* is inherently contrarian. As Dudek put it, *avant-garde* is "by definition art that is ahead of its time, that is shocking, disturbing, and therefore viewed as socially objectionable. Its specific aim is to undermine the existing order and to replace it with another. It attempts to do this by contradiction, challenge, confrontation, and self-assertion."

Turning from the visual arts, consider next Bruce Lee. He developed an original system of martial arts – Jeet Kune Do – but had to fight the established, traditional schools because they did not want to teach any such techniques outside of Asia. Bruce broke with tradition.

Howard Gruber described how the famed developmental psychologist Jean Piaget used several specific strategies. First, Piaget always thought with a pencil in his hand. This is a simple but useful tactic, given how fleeting creative insights can be. Second,

Piaget read outside his own field. Third, he did not read inside his own field. And last, he always had a target or “whipping boy.” The last of these implies working independently, imagining one’s critics, which is a kind of contrarianism. B. F. Skinner also suggested that scientists read outside their own field. This too is a kind of contrarianism, or at least increases the likelihood of it. Avoiding one’s own field is even more contrarian.

Dr Seuss, prolific author of children’s literature, broke rules on every page of every book. He made up his own words, used many an ungrammatical sentence, and defied the laws of physics in the actions of his characters. Gertrude Stein and e. e. cummings also come to mind; they too broke certain literary traditions.

Although instructive, these cases – Disney, Gandhi, Heimlich, Ellington, Freud, Picasso, Piaget, Skinner, Seuss, Stein, and Cummings – are famous creators. Generalizations from them are therefore questionable. As noted above, case studies are always only examples, not evidence.

Contrarianism in the Service of Creativity

Two distinctions will help to determine when contrarianism is in fact associated with creativity. First is the distinction between contrarianism and oppositional thinking. The former is intentional and the latter an unintentional tendency toward nonconformity and unconventionality. Similarly critical is the distinction between contrarianism that is intentionally used for the sake of creativity, and that which is used merely to insure originality and salience. Contrarianism does not guarantee creativity; it can have other outcomes or be directed to other objectives, including originality. But originality does not insure creativity; it is necessary but not sufficient. It follows that contrarianism for the sake of originality may lead only to deviance and not to creativity.

Salience is a possibility because contrarianism does lead to originality – the contrarian is different and unique – but it may just attract attention without actually introducing a truly creative idea or act. Original behaviors and actions are salient and thus do grab our attention. Creativity, on the other hand, probably is much more likely when the intention is creativity rather than mere salience or popularity. This is *contrarianism in the service of creativity*. When that is the intention, there is likely to be some fit, appropriateness, or effectiveness, as well as originality. Recall here that creativity requires both originality and effectiveness. Contrarianism only contributes to the former and can inhibit the latter.

Even contrarianism in the service of creativity has potential problems. First is what I once called *misplaced investments* (Runco, 1995). This occurs when the creator uses a contrarian tactic, but does so to the extent that he or she is investing time into being different and therefore not investing time and energy into the topic or problem itself. The investment is misplaced because time invested into being different is often time away from good focused work. This is especially problematic because quite a bit of research suggests that persistence and immersion is often a requirement for creative insights and breakthroughs.

A second potential problem is that contrarianism can lead the individual to break rules that should not be broken. It may be that the creator is reinforced for contrarianism because it leads to creative insights, but then fails to exercise discretion and applies the same tactic in areas where some conventionality should be respected. The proposals from Feldman, Gardner, and Csikszentmihalyi in 1999 and Gruber in 1993, that moral and humanitarian values should be clearly encouraged along with creativity, are relevant here. If contrarianism leads the individual to break the important rules that keep society running smoothly, we have an example of what Robert McLaren called *the Dark Side of Creativity*. Examples of this were given by Russell Eisenman and Richard Brower in the Special Issue of the *Creativity Research Journal* which was devoted to Creativity and Deviance. Brower provided long lists of eminent creators who spent time in jail. A more recent branch of this research used the term malevolent creativity. Even more recent empirical work by Jack Goncalo demonstrated how very simple decisions (e.g., about diet) that involve a disregard for rules have clear implications for when individuals have opportunities to act creatively.

Creativity as Postconventional Contrarianism

One useful way to think of contrarianism is as postconventional creativity. The term postconventional originated in developmental theories. It is a mature stage of development and follows the preconventional and conventional stages of development. A child in the first of these stages is unaware of rules, norms, and conventions, and in fact does not recognize the value of rules. His or her games are ever-changing; there are no stable rules to keep the child moving toward an objective. Moral judgments at this age are based on rewards and punishers rather than a sense of right and wrong. The child is, however, often quite creative in art and expression. Ask a group of preschoolers to draw pretty trees and you will get trees with pink, purple, and polka-dotted rather than green leaves. Preschool children pick their colors based on preference rather than convention. They are highly self-expressive, and that can be a very good thing for creative behavior.

Individuals in the conventional stage are well aware of rules – and in fact hold to very literal interpretations of them. They see the value of conventions. Conventional behavior allows them to fit in with one’s peer group, for instance, but sometimes the conventional individual puts too much effort into doing just that. The result is a tendency away from anything unconventional and original, which means that creativity is not possible. Conventional individuals respond to peer pressure and hate bending rules. This explains the fourth-grade slump in creativity, when many children become noticeably less original in their ideation. Conventionality also leads them to a literal use of language, and it certainly is apparent in their playing games (completely by the rules rather

than improvising as needed) and in their art. Children in this stage are likely to only draw trees that have green leaves. Not a polka dot in sight.

The third stage is postconventional. Here the individual is aware of rules, norms, and conventions, but make decisions for him- or herself rather than blindly conforming. Conventions are taken into account, but so is the immediate context. If asked to draw “what trees look like,” leaves may very well be green, but if asked to draw a beautiful tree, the leaves may include rainbow colors or whatever color is the individual’s favorite. This same capacity to recognize conventions but think for one’s self is exactly what was meant earlier by exercising discretion. With discretion, contrarianism will be used appropriately, in the service of creativity. Without discretion, contrarianism is blind and constant, probably oppositional rather than adaptive and effective. Contrarianism must be mindful to capture the originality and effectiveness that are both required for creativity.

Corporate Creativity

A corporation is a company or group of people authorized to act as a single entity, and everybody interacts with corporations in many aspects of their lives. At the most transactional, individuals buy goods produced by a corporation. However, many people also interact with corporations more indirectly through consuming sporting events (e.g., corporate sponsors and advertising) and philanthropic activities. Corporations even hold political sway through financial donations and interest groups influencing policies or candidates. Interactions with these firms drive the economy and are critical in the society operates.

Outside of the business aspect, corporations have the ability to fundamentally alter the way people interact with each other and the environment. In large part, these changes are due to creativity and innovation that emerge from the corporate entity. In 1913, Ford introduced the assembly line, which reduced the production time of a car by nearly 80%. Further, the gains in efficiency while maintaining consistency ushered in a societal shift to more individuals being able to purchase cars. Assembly lines are not considered creative at this point due to the widespread adoption of the practice.

In a more recent example, Facebook is 18 years old at the time of this article. Not only has Facebook experienced financial success, but has registered 2.27 billion active users in less than two decades. There were competing social media sites at the time of Facebook's inception (e.g., MySpace), but the way in which users could interact through the platform was novel. It is hard to imagine a world today without connecting with individuals through some social media no matter the aspect of one's life (e.g., professional connections through LinkedIn). Innovative product development by corporations includes the Apple iPhone released in 2007 with their patented touchscreen. Within 2 years, Android released similar products, and the touchscreen is now synonymous with smartphones. When Apple first produced their phone, Nokia and Research In Motion (RIM) held sizable portions of the smartphone market share with limited touchscreen capabilities. Through products, process, or environments, corporate creativity is arguably a change agent in society.

This article offers a refinement for the definition of corporate creativity by separating organizational influences on individual creativity and the creative outputs of a corporate entity. To achieve this refinement, a three-part, multilevel framework of creativity strata is presented. Based on this framework, there is a discussion of how corporate creativity is influenced by top management teams, organizational resources and strategies, and organizational cultures and climates.

Creative Strata

Creativity is a complex, multifaceted construct. Rhodes' four Ps of creativity provided a useful framework for studying creativity. In this framework, creativity is examined in relation to the person, product, process, and press (i.e., environment). Further, researchers often attempt to explore the interplay between the facets (e.g., [Royston and Reiter-Palmon, 2017](#)). For example, how might creative personality factors operate through cognitive factors to influence creative output? The four P framework, however, is mainly focused on the individual level of creativity. Even when researchers examine organizational or environmental factors (creative press), the focus typically rests with individual and team creative outcomes (e.g., [Navarrese et al., 2014](#)). Less research has examined how creativity is conceptualized at more aggregated levels. The different facets of creativity also need to be considered in the level of creative analysis. This article will discuss creativity in terms of three strata: microstratum, mesostratum, and macrostratum.

At this point, a majority of creativity research falls within the microstratum. At this level, the unit analyzed is the individual. The goal of the research is to understand the factors that influence individual creativity whether that be personality factors, interactional phenomena, or environmental influences. At the mesostratum, the focus is the conglomeration of individuals into teams or multi-team systems. The focus is not on the individual production, but rather the creativity at a team or multiteam level.

This shift in level does not negate the four Ps framework. For example, researchers could examine how cultural influences or leadership practices influence a team's performance (creative press factors). Further, researchers could explore how multiple teams communicate in their production of a creative solution (creative process factors). In these examples, the unit of analysis shifts from the individual (i.e., microlevel) to a broader, team level (i.e., mesolevel). At the highest level, the macrostratum would encompass the conglomeration of teams and individuals into a corporation, or a system of corporations (e.g., an industry). Again, the four Ps framework is still useful at this level, but as with examining teams, the unit of analysis shifts to the corporation. For example, researchers might examine how the creativity and innovation emerging from Bayer or Pfizer impact the market with a novel drug.

Arguably there are additional levels researchers could explore that are above the corporation level. For example, researchers can examine movements and their creative outputs. An example would be the Cold War arms race between the Soviet Union and the United States, which spurred innovative technologies resulting in the advent of space travel. However, these broad concepts are outside the focus of this article. As the unit of analysis and outcomes become more abstract, previous frameworks do not need to be abandoned. We believe the facet frameworks such as the four Ps most likely transcend our strata.

Much like decisions regarding which statistic to use, this framework is predicated on the types of questions researchers are attempting to answer. If a researcher is only interested in the individual or team output, then the focus should be directed in those strata. However, if researchers are interested in corporate creativity, then the unit of analysis and outcomes must reflect this question. This framework is offered with the goal of advancing thought processes in exploring more aggregated creative efforts. It is this type of framework that will be used to discuss corporate creativity, which we believe is nested at the macrostratum.

Corporate Creativity Defined

Creativity is the production of an idea, solution, or product that is both novel and useful. For something to be creative it must have both component parts. This definition should transcend levels of creativity. Said another way, no matter it being an individual or corporation, creativity is built upon novelty and utility.

The research investigating organizational creativity provides multiple definitions for the construct. [Robinson and Stern \(1998\)](#) defined a company as creative "when its employees do something new and potentially useful without being shown or taught" (p. 11). This definition is more akin to the individual and team levels, and the definition does not best capture corporate creativity. Earlier, [Woodman et al. \(1993\)](#) offered a more holistic definition of corporate creativity: "The creation of a valuable, useful new product, service, idea, procedure or process by individuals working together in a complex social system" (p. 293). Returning to the framework presented here, we argue that corporate creativity would be the conglomeration of individual- and team-level factors. However, the work by [Woodman et al. \(1993\)](#) still appears to rest on the unit of analysis being the individual or team rather than the corporation. Turning to the innovation literature, [Damanpour and Evan \(1984\)](#) offered that corporate innovation was, "the implementation of an internally generated or borrowed idea [...] that was new to the organization at the time of adoption" (p. 393). In this last definition, the unit of analysis rests at the corporation, and the definition contains both novelty and utility.

Although nuanced, the definition of corporate creativity matters both for the core components and the level. To synthesize the work of [Woodman et al. \(1993\)](#) and [Damanpour and Evan \(1984\)](#), we offer that corporate creativity is the production of novel and useful products, processes, ideas, or solutions through the interactions between complex corporate structures. This definition captures the contextual environment, the unit of analysis (i.e., the corporation), and the component parts of creativity. This article will discuss top management teams, organizational strategies, and cultural factors that influence the creativity of the corporation.

Top Management Teams

Top management teams (TMTs) are the upper echelons of an organization (e.g., board of director members, chief officers, etc.). These individuals typically have the power to allocate resources, hire middle-management personnel, and determine project prioritization for the organization. Furthermore, the TMT is primarily responsible for setting the strategic vision. From this vision, the TMT builds structures and teams for employees to carry out the projects needed to achieve the vision. Moreover, the TMT can build norms for how work is completed and what the expectations are for completing the work. Due to the critical position and decision-making power, the TMT is a unique group of individuals who have the ability to influence the way in which creativity manifests in the organization. According to this top echelon perspective, the corporation ends up being a manifestation of the TMT ([Hambrick and Mason, 1984](#)). This ability to shape the nature of the corporation and the characteristics of this group may influence how creative the corporation can be. The characteristics of the group are typically researched in terms of the diversity of the TMT.

Diversity can be divided into demographic and functional diversity. Demographic diversity refers to those characteristics salient to others (e.g., age, race, gender, etc.). Functional diversity refers to the mix of specialization and expertise within a group ([Bunder-son and Sutcliffe, 2002](#)). Diversity has shown mixed results on the effects of team-level creativity. The major conclusion from teams' research is that demographic diversity may not be an effective facilitator of creativity within teams, but functional diversity may be a more effective influencer ([Reiter-Palmon, Mitchell and Royston, 2019](#)). Specifically for this article, the functional diversity of the TMT, measured by the business area the members came from, positively impacted firm creativity ([Yoon et al., 2016](#)).

One explanation for the increased effectiveness of functional diversity is that this type of diversity more easily highlights task conflict. When task conflict occurs, previous research indicates more creativity to emerge from the individual or team. However, task conflict can be difficult to separate from more relational conflict. Camelo-Ordaz et al. (2014) cautioned that the high correlations between relational and task conflict could mask the potential benefits of task conflict. Effective TMT teams need effective social processes to manage the conflict types to focus on task management (West and Anderson, 1996).

Diversity and any resulting conflict depends on whether the TMT values creativity. A company can have a multidisciplinary team that is full of individuals who want to maintain the status quo. In this case, the functional diversity may not lead to increases in company creativity. Further, individuals within the TMT may value more radical or less radical ideas, which would influence how radical the creativity emerging from the corporation is (West and Anderson, 1996).

TMT should be the factor of interest in corporate creativity rather than a single leader. Although corporations may have a singular, prominent leader, rarely are all decisions and resulting corporate creativity dependent on one person. For example, Elon Musk, Steve Jobs, and Warren Buffett are all individuals who are prominent figures within their respective firms; however, any innovation emerging from the corporation has input and efforts from a team of senior leaders. Examining singular leaders and their influence on creativity is out of the purview of this article.

The TMT is the group of individuals that truly drive the direction of a company. By having a high-functioning, interdisciplinary team that values creativity, the corporation's creativity may be heightened. At the microstratum level, we envision the effects of the TMT to manifest through organizational support for creativity or manager's support for creative behaviors. At the mesostratum, we argue the effects of the TMT to influence a firm's creativity through the vision, strategies, and structures put in place.

Organizational Resources and Strategies

A strategy is a plan with a clear aim or goal. For organizations, strategies are important for change initiatives, product development, and resource allocation. An organization's ability to find opportunities and develop strategies to exploit that opportunity is critical in maintaining competitive advantages.

Often firms are faced with paradoxes on how to best allocate resources for creative efforts. At the core, a successful business has products and processes that have generated stable and predictable delivery of goods as well as stable and predictable returns. This stability does not always allow creativity to emerge. Paradoxes are coexisting, ongoing tensions that have competing demands and are not typically solved with one-time solutions (Smith and Lewis, 2011). Specifically, firms can explore or exploit their resources in the pursuit of creative efforts. Explorations focus on longer-term investment in creative actions; whereas exploitations focus on the shorter-term and current processes to produce creative outcomes (Smith, 2014). Shorter-term resource allocation may result in more incremental creative outcomes; whereas longer-term resource investment may result in more radical creative outcomes. For example, a company that tweaks their production model through Lean processes may see a short-term bump in production through the creative retooling of the line; however, a company that invests in research and development may have a breakthrough, patented product that boosts the company well ahead of the competition.

In the leadership research, balancing the exploitation and exploration has been termed ambidextrous leadership (Zacher and Rosing, 2015). We argue that corporations can be ambidextrous as well. Part of this ambidextrous nature can come from leadership decision-making, but it can also be influenced by a culture of competition, strategic organizational actors (e.g., market research teams), or the vision produced by the TMT. This ambidexterity is a reflection of these organizational factors. Corporations that have highly competitive cultures and an aggressive TMT may focus heavier on short-term gains and incremental creativity (e.g., more reliance on exploitation). These actions can sometimes be seen when companies are taken over and then sold off piecemeal. Conversely, organizations may have an increased chance at more radical creativity by investing resources in longer-term projects, but the organizations may open themselves to potential competitive disadvantage by not innovating. As with many organizational constructs, the ambidexterity of an organization rests in that middle ground where successful companies must exploit and explore with resources allocated to creative efforts.

Cultural factors may also influence the exploitation/exploration paradox. Specifically, there appears to be a factor of speed, meaning short-term and long-term investments are relative to the rate at which the innovation is occurring. For example, a company that has a fail-fast mentality may be ambidextrous, but their longer-term exploration may be heightened by the rapid iterations of product development and testing. A more concrete example would be the development of the reusable rocket for space flight. SpaceX developed and successfully tested a reusable rocket in roughly 10 years. In the course of that decade, the company suffered multiple, public failures. However, the senior leadership, headed by Elon Musk, had instilled a culture of failing fast to increase the rate of creative production. Arguably, the entire process was a mix of exploiting the current processes for incremental creativity, and longer-term investment in technologies that resulted in a fairly radical innovation in rocket technology.

Besides the allocation of resources, there is a consideration of the availability of resources (i.e., the supply of inputs). Resource slack and constraints have been examined for how they influence individual and team creativity. Researchers found that the slack of resources can spur growth due to the increased investment a firm can make in innovative efforts; however, resource constraints can also force companies to adopt more creativity means to make the resources stretch further. In reality, it appears that the relationship between resources and creativity is curvilinear. There is most likely a Goldilocks zone where individual creativity is heightened and

either too much or too little resources are detrimental. Moving this above the individual, companies that are creative most likely have found a balance of resource allocation by being more ambidextrous.

One resource that is critical to corporate creativity is its creative capital, which is the pool of creative thinkers that generate ideas leading to valuable products (Florida and Goodnight, 2005). According to Florida, a third of the US population is comprised of the so-called creative class, which is made up of “professionals whose primary responsibilities include innovating, designing, and problem-solving” (Florida and Goodnight, 2005). Leveraging the pool of creative class individuals within a company is one challenge; the other strategy is how to select and retain that pool, or arsenal of talent, to ensure continued corporate creativity.

Human resource development (HRD) is a framework of building the talent pool within an organization. The strategies behind HRD include the practices that would align with the vision and TMT in pursuit of creativity and innovation. As Gibb and Waight (2005) argued, HRD is already concerned with individual factors that lead to increased creativity so it is time to link these strategies to larger organizational policies. In essence, it is time to link HRD practices to the larger macrolevel of analysis. In a review of the literature on improving creativity in organizational settings, Reiter-Palmon et al. (2019) discusses how organizations can select and train for creativity. Knowing that creativity can be something selected and trained for, HRD executives can logically expand on the previous work to move our discussion to a higher level. The strategies around setting the pipeline for creative individuals ensure there is lifeblood for corporate creativity. This pipeline is built through HRD strategies and can be determined by visions or goals set forth by the TMT. As was discussed with the diversity of TMTs, diversity of thought and experiences can vastly improve or hinder the level of corporate creativity. Those corporations who better develop their recruiting and selection processes to bring in innovative diversity are ensuring continued improvement.

Selection is only half of the human resource strategies. Training and development are important factors to increase the collective talent in the organization as well as retain individuals who are currently in the organization. Retaining the creative class appears to be a critical component to maintain corporate creativity. To this end, corporations that have more mature training and development programs may see increased yields in creative production. Again, it is not the aggregation of individuals selected, but it is the formation of an effective HRD strategy that dictates the recruitment, selection, and development of a workforce that can then influence the level of corporate creativity. Further, the HRD strategy should reflect the culture of the organization and the vision set forth by the TMT.

Organizational Culture and Climate

Organizational culture is the shared norms of the system that dictate behavior. Culture and climate are two of the most researched areas in the organizational creativity and innovation fields. Research has found increased creativity emerges from support for risk-taking, support from top management, challenging work assignments, autonomy, intellectual stimulation, and positive relationships with peers (for review, see Reiter-Palmon et al., 2019). A culture that provides members with meaningful, challenging work where they feel supported is critical for individual creativity. The culture of an organization can be determined largely by the TMT, where the leaders set forth expectations for what is and is not acceptable in the company. In this way, TMT can institutionalize creative efforts into the fabric of the company. Further, supportive peers and challenging work assignments can be determined by factors such as the HRD strategies the company has in place. Understanding your workforce and selecting appropriate individuals will help strengthen the culture and build the climate of safety and support needed for creativity. Further, the HRD can assist in providing challenging opportunities through programs such as institutionalized stretch assignments, job shadowing, job rotations, and high-potential programs. Together, a supportive TMT and appropriate HRD can create an organizational culture and climate that may lead to increased firm creativity.

Measuring Corporate Creativity

Corporate creativity has been discussed in terms of different strata. Specifically, this article focused on the corporate, or macrostratum of creativity. With this focus, the unit of analysis becomes the corporation rather than individual and team outputs. In this regard, the measurement approach must evolve. As it stands, the focus has been on how organizational factors influence individual outcomes. To truly measure corporate creativity, organizational-based outcomes must be adjusted.

As mentioned earlier, corporate creativity is not necessarily the aggregation of individual creativity. Yoon et al. (2016) provided an example of how corporate-level creativity might be measured by using externally based ratings of the company. Other measures might include impacts within the industry, or shifts in industry direction emerging from the firm. This measurement level is challenging and has not received the attention the individual level has. However, there is no need to discard the four Ps framework. For example, the processes an organization implements or develops to influence its creative outcomes can be examined (e.g., Damanpour and Evan, 1984).

A caution when measuring corporate-level creativity is that performance and creativity are not equated. Return on investment and corporate financial performance are not measures of creativity. These outcome variables may be linked to creative efforts, but it would be folly to use these as a proxy variable for creative performance.

Conclusion

This article introduced our framework of creativity strata, and discussed how TMT, organizational resources and strategies, and organizational climate and culture influenced corporate creativity. As creativity researchers continue to explore organizational phenomena, we recommend further work in conceptualizing the level at which we are interested. In addition, the macrostratum needs additional measurement formulation.

Research in corporate creativity is useful in the extent it is translational. From a practitioner standpoint, there are recommendations that can be gleaned from this article. First, a TMT that is functionally diverse and values innovation should lead to increased firm creativity. Second, a more ambidextrous company that has strategies concerning its human capital around innovation should lead to increased firm creativity. Finally, the outgrowth of the TMT and strategies should lead to a more supportive culture and climate that lead to increased creativity.

Introduction

In the first part of the chapter, we introduce and consider craft from the perspective of mainstream cognitive science which defines creativity as an attribute of an individual human mind. Specifically, we consider the information processing model which takes the computer to be a metaphor for the brain and which frames creativity in terms of the discovery of novel and innovative solutions. We then contrast this view with craft which, through its activity, respects and seeks to foster skilled working techniques using traditional materials. Viewed in this way, craft does not appear to provide a suitable platform for exploring innovative solutions, nor to draw upon the human mind’s capacity to be creative as defined by mainstream cognitive science.

In the second part of the chapter, we change perspective and concentrate on the process of crafting rather than on its outcome. In doing so, we propose an alternative definition that equates creativity with the development of circumstances that facilitate uncertain or unpredictable consequences. Far from a nostalgic backwater of human activity, this interpretation presents crafting as an activity that creates its own future and, in so doing, highlights as well as undermines certain fundamental assumptions that are made within traditional cognitive science about the nature of intention and of agency and about the location and function of the human mind.

The Meaning of “Craft”

“Craft” is an odd word. As a noun, it is somewhat ambiguous. It may be used to describe a domain of activities requiring skills acquired through training and experience. So far so good, but it may also refer to the outcome of these skilled activities in a way that implicitly but mysteriously distinguishes craftwork from art-works, from the outcomes of mass industry and from the products of scientific endeavour.

For example, keyhole surgery is not generally considered a craft whereas the work of a locksmith is. It is not altogether clear what distinguishes these two activities. “Craft,” as a verb, is altogether more straightforward. It describes a skilled gesture that arises from training, experience and tradition. As will become apparent, whether or not “craft” is seen as a creative activity depends a lot on whether we use “craft” as a verb that refers to a masterful performance or as a noun referring to a product or profession. In order to understand why this should be, it is necessary first of all to look at how we understand creativity.

A History of Psychology in 500 Words

Within the domain of psychology, creativity is commonly understood to be a process that takes place within the human mind and that leads to the production of a new and useful innovation or product. In light of the opening paragraph, it is immediately apparent that this mainstream psychological understanding defines creativity by the outcome of a process rather than by the nature of the process itself. In order to be able to map the relationship between creativity and craft, it is important to understand why this particular view of creativity gained traction within psychology.

For this purpose, we can situate the beginnings of the modern science of psychology with the establishment of two laboratories in the 1870’s. One was founded by William Wundt in Germany, the other by William James in the United States. The research that took place in these two labs was predicated on two quite different theories of the mind and the tension between these two positions

has influenced the nature of psychological research ever since—including research into creativity. Wundt believed that the way to understand the human *psyche* was to begin by determining how the process of thinking was organised. Effectively, Wundt's aim was to create an anatomy of the mind. This approach came to be known as structuralism and its immediate philosophical antecedents can be found in the writings of Descartes although, as we will see, they can also be traced back to Aristotle.

In contrast, James' functionalist approach to mental activity focused efforts not on the structure of thoughts, but on what thinking did in relation to the world. Functionalism was associated with the development of a contemporary philosophical movement known as pragmatism and has its roots in the writings of Darwin. The most dominant psychological model of the 20th century, B.F. Skinner's learning theory, took functionalism to an extreme by excluding the notion of mind altogether and concentrating exclusively instead on the study of an organism's reaction to environmental stimuli. In 1959, Noam Chomsky launched an influential attack of Skinner's model of verbal learning and, by extension, on behaviourism in general. Chomsky argued that a model of infant language acquisition based exclusively on learning, in the absence of an innate language structure (what Chomsky termed a "Universal Grammar") could account neither for the rapidity nor the flexibility of language learning. This heralded the so-called Cognitive Revolution in psychology and the creation of a new discipline, Cognitive Science. In the revolutionary fervour, cognitivism not only denounced behaviourism, but dismissed functionalism in general. As a result, for the last 50 years, cognitive science has situated itself firmly within a structuralist framework and an information processing model of the mind has developed, influenced by the powerful notion of the computer as a metaphor for the brain.

No Room for Craft in Conceptual Space

The computer metaphor suggests that the brain takes in information and organises it into a representation of the world. This internal representation can then be used as a decision-making tool in order to produce an appropriate response to the environmental situation on which the model is based. The role of Cognitive Science is to map out this decision-making process, to identify its various stages, and to describe the nature of the data manipulation that takes place. This view of cognition has two important consequences for how we see creativity.

First, it locates the act of creation in the brain and identifies the human (or at least the human brain) as an active and intentional creative agent. We have an idea and, if we think it is a good one, we take the necessary action to bring it about. The view of humans as active agents who create their own destiny by imposing their will upon the world certainly chimes with the pervading western anthropocentric, post-enlightenment manifesto. By giving an ideational origin to creation, the information processing model draws a clear and linear direction of causation from the brain to the environment. Given that the birth of Cognitive Science was a direct reaction to behaviourism, it is probably no coincidence that learning theory predicts the exact opposite causal relationship. For Skinner, it was environmental conditions that determined human behaviour.

Second, and quite consistent with structuralism, the information processing model envisages the mind as a virtual space. For example, in her influential book, *The Creative Mind: Myths and Mechanisms*, Margaret Boden (2004) suggests that creativity occurs within, what she calls, a conceptual space. An example of a conceptual space from the domain of craft might be the schema for a cup. A conceptual space sets constraints on what can and cannot be classed as a cup. The creation of an innovative cup can occur in one of two ways. First, it may take place by searching for undiscovered possibilities that might exist within the confines of the pre-existing conceptual space. Second, Boden describes a more radical form of creativity in which a creative solution is found not within the conceptual space, but by changing the shape of the space itself—perhaps by dropping a constraint or converting a constraint into its opposite. With regard to the cup, this would require conceiving of something that was not a cup and yet, once it was brought into existence, had the effect of stretching our understanding of what a cup could be by expanding the conceptual space for "cupness."

Taking this cognitivist understanding of the mind and applying it to the domain of craft gives the impression that, far from facilitating creativity, craft represents the antithesis of novelty and innovation. By respecting traditional, skilled work practices, the crafts-person understandably turns his/her gaze towards the achievements of the past rather than the possibilities of the future. In addition, craft professions or guilds are organised by material: stone-masonry, carpentry, ceramics, etc. The properties of these materials, which lie at the heart of a craft guild, do not change. Travertine is the same material now as it was when Roman masons used it to build the Colosseum. It seems clear that traditional work methods combined with the timelessness of ancient material is not an ideal partnership with which to explore and extend the limits of conceptual spaces. Turning to the history of craft and its relationship with other cultural activities, past and present, the impression of craft as the antithesis of creativity becomes even stronger.

The History of Craft and the Birth of Art

During Plato's time, the Greek words *techne* and *episteme* both referred to knowledge. According to Heidegger, Plato uses the two words interchangeably. However, in post-Platonic ancient Greece, *techne* was increasingly used to refer to the sort of knowledge necessary to perform a craft or trade, what we now call "tacit knowledge," leaving *episteme* to refer exclusively to abstract or intellectual knowledge. In addition, the distinction between the two began to establish a hierarchy in which *techne* was viewed as an inferior form of knowledge to *episteme*. The devaluation of manual know-how and the differentiation of doing from thinking,

remains deeply embedded in western culture to this day. Indeed, the education systems of most developed countries are predicated upon it.

Given this historical backdrop, craft's position in the creative doldrums would not be surprising were it not for the fact that its close cousin, art is viewed as the quintessentially creative domain. In his book, *The Craftsman*, Richard Sennett (2008) uses details from the autobiography of the renaissance goldsmith Benvenuto Cellini to explain how this situation came about. In ancient Greece, no distinction was made between art and craft and none was needed: the concept of art as we know it today did not exist. This situation continued into the middle ages by which time crafts, including painting and sculpture, were organised into strictly controlled guilds. When a young person, usually a boy, entered a seven-year apprenticeship, the workshop literally became his home; with the master craftsman *in loco parentis*. The apprentice learned the skills of the trade before going on to spend a further 7 years as a journeyman around Europe, during which time he learned how to put these skills into practice in different social and material contexts. Sennett emphasises the extent to which guilds, craft and apprenticeships were embedded within the community. This collective approach was encouraged by the guilds by, for example, advertising the place of origin of a product rather than the identity of the workshop or its master.

In this context, Cellini, a master goldsmith, began changing the traditional approach to working with gold with significant social and cultural repercussions. Cellini's workshop began to produce scenes or pictures with gold in a way that was similar to the approach of painting or a sculpture. In so doing, Cellini moved away from making objects as products and towards conceiving of objects as vehicles of expression. Significantly, what these objects came to express (or at least were seen to express) was the inner character of Cellini. This had important consequences. It meant that Cellini broke away from the communal anonymity of the guild system. He became rich and famous, not by, for example, the selling of a simple salt cellar, but by creating a unique salt cellar that expressed part of Cellini. Cellini became a brand. No one else was able to express Cellini like Cellini could. The value of the brand depended not only upon the skill but upon the character of Cellini. In this way, the concept of a creative personality developed out of the original role of master craftsman.

To summarise, the renaissance period begins with the birth of conceptual twins: art and artistic genius. The act of creation was transformed from a communal endeavour to an elite activity. Art was able to emerge and escaped the confines of craft and its social structure by redefining creativity as the expression of the internal emotional and cognitive turmoil of the artistic temperament. Interestingly, Sennett describes how, the contemporary renaissance philosopher, Pico della Mirandola understood the development of the artistic temperament to be an indication of a wider development of human self-determination and coined the term *Homo Faber* to mean "Man as his own maker."

Creative Thinking

Let us take stock of where we have got to. We began by suggesting that mainstream psychological models couch creativity in structural terms, locating the origin of creativity in the mind which, in turn, is housed in the brain. Second, we saw that from ancient times, thinking-with-the-mind has been considered to exist on a separate and higher level from thinking-with-the-hands. Indeed "thinking" and "mind" are now so inextricably linked with the brain that thinking-with-the-hands is almost an oxymoron. Third, we saw that art came into existence when the manual activity of a goldsmith made a paradigm shift between these two levels. This shift occurred when it became accepted that the creative output of the goldsmith was predicated on the unique, personality of the artisan. Taken together, these three points suggest that creativity is essentially viewed as an intellectual activity with the manual activity of craft therefore lying beyond the pale of western creative endeavour.

Creative Doing

Having established, from a structural perspective, that creativity has a limited part to play in the domain of craft, we would now like to return to our opening statement and explore what happens to the notion of creativity and of thinking in general when we consider "craft" as a verb rather than a noun—that is, as a word that describes the gesture of crafting rather than its outcome. We will show that a very different picture of what it is like to be a human involved in a creative activity emerges when we focus on the process of craft rather than on the structure of the mind (see Glăveanu (2017) for a summary of the psychological research on the relationship between creative action and craft). The study of ontology is concerned with investigating the nature of being and it will become apparent that craft, as a process, reveals an ontological framework that is more aligned to the functionalist psychology of James and the philosophical pragmatism of John Dewey than the structuralism of Wundt and Descartes.

At beginning of the 20th century, in his book *Creative Evolution*, Henri Bergson (Bergson and Mitchell, 2009) swam against the tide of more than 2000 years of western cultural development by proposing that the defining emergent evolutionary feature of the human intellect was not "wisdom" but "making": In particular, he drew attention to the human propensity to use tools to make further tools and suggested re-classifying *Homo Sapien* as *Homo Faber*. As we have seen, it is not the first time someone has used *Homo Faber* to refer to our species. But, when Pico used the term during the renaissance, he was articulating the view that man had a hand in the creation of his own internal character. If we now consider Pico's internalist assertion in the context of Bergson's emphasis on tool-making as the defining human cognitive activity, we can see that man-as-his-own-maker can also be externalised to refer to the way in which a craftsperson might observe the unfolding relationship of hand, tool and chosen material that takes

place before his/her eyes. Rather than seeing thinking as the exclusive domain of neural activity, it becomes possible to envisage cognition as a process whose focus is to be found, not in the brain, but in manual activity—in what Kirsh and Maglio (1994) refer to as “epistemic action.” For example, instead of seeing a drawing as the representation of a cognitive event (and the outcome of manipulating a conceptual space) Ingold, (2013) in his book *Making*, concentrates instead on the movement of the pencil across the paper. This change of register reveals drawing to be an act of discovery, making it possible to envisage design as happening, not in the head, but in the improvised tracing of a line.

Drawing as an activity of discovery emphasises the unpredictable nature of creativity. In *The Nature and Art of Workmanship*, David Pye (1995) noted the extent to which an industrial manufacturing process is designed to be entirely predictable. He refers to this as “the workmanship of certainty” and contrasts it with “the workmanship of risk” of craft practice in which:

the result of every operation during production is determined by the workman as he works and its outcome depends wholly or largely on his care, judgment and dexterity (Pye, 1995, p. 52).

Ingold and Pye formulate creativity neither in terms of the pursuit of novelty and radical change nor as the outcome of a divergent thinking style within one of Boden’s conceptual spaces. Rather, they introduce the idea that bodily actions that facilitate unpredictable situations are, *de facto*, creative. Given the inescapable fact that bodily action always takes place in the world, the reformulation of creativity as an agent of uncertainty also implies that creativity must arise out of a delicate balancing act between, on the one hand, the craftsperson’s actions and, on the other, the influences of the environment upon the craftsperson.

Ironically, the structuralist model of the mind portrays creativity as a retrospective action (the physical object is a representation of a pre-existing mental concept) whereas Pye’s use of the word “risk” implies that the experience of the craftsperson is one of creative anticipation. So, by focusing on action rather than outcome, craft is transformed from a domain that is nostalgically attached to past traditions into a force that is directly implicated in creating its own future. This fundamental change in perspective reconfigures the environmental architecture of creativity in two interesting ways.

First, “the workmanship of risk” paradoxically reduces the risk of accidents to almost zero. In a “workmanship of certainty,” an accident can be defined as a departure from the pathway whose direction and outcome has been defined in advance. In the “workmanship of risk,” the outcome is not predicted in advance. It is the process itself that brings about the future and so the concept of an accident as an undesired state loses all meaning.

Second, craft-as-action undermines the concept of creative constraint. The structural model of creativity is predicated on an ancient Aristotelian notion called Hylomorphism (from *Hyle* meaning matter and *morphe* meaning form) which posits that any object can be divided into the matter of which it is made and the form that matter takes. Hylomorphism prepares the ground for a hierarchal model of creation based upon the notion that human intention imposes form on inert matter. In contrast, the process of crafting suggests a collaborative exercise between human gesture and the properties of materials. The craftsperson experiences material as an essential partner in a distributed creative system rather than as a dead weight against which he/she must pit his/her will.

In this section, we have begun to consider the significant repercussions of re-naming ourselves *Homo Faber*. With man as a maker and creativity as a process, the locus of cognition moves out of the skull towards the point where the process is visible—between the hands. With the *dura mater* no longer marking its boundary, the spatial coordinates of the mind become fluid—determined instead by the activity in hand. This has implications for what we understand to be the driver of creative activity. With the mind in the head, agency also automatically locates itself there. However, once things in the world become part of the creative activity of the mind, it is difficult to see how we can continue to describe material as lacking agency. In the next section, we will present a theoretical model of the mind that is explicitly predicated on the notion of material agency in the context of a spatially extended mind. This, in turn, will enable us to describe an ontology which includes craft but extends beyond its frontiers and which establishes creativity as a recursive process in which man is shaped by the tools he makes and the material he uses.

Material Engagement Theory

Material Engagement Theory (MET) was first introduced by Lambros Malafouris and Colin Renfrew within an archaeological context in a collection of essays edited by DeMarrais et al. Renfrew (2004) and further developed by Malafouris both within archaeology (2013) and also through the anthropological study of contemporary pottery making (2008). MET is far from being the only systemic account of making. To name but two others, Ingold (2013) describes a similar ontological position in his book, *Making* and Anthony Chemero (2009) addresses the issue from within a Cognitive Science framework in *Radical Embodied Cognitive Science*. We have chosen MET because, by observing potters at work, Malafouris has been able to make explicit links between the behaviour of material, the meaning of material change, and the relationship between material transformation and human cognition in a way that is entirely consistent with the process of craft as we have been describing. Below, we summarise four important principles of MET before going on to present a short case study in order to show how these principles manifest themselves in action.

The Extended Mind: As we have seen from the example of drawing, cognition can be said to happen not in the head but on the page, at the point where graphite touches paper. Cognition is enacted through an active relationship between human and material.

Material Agency: Instead of viewing agency as a human attribute, the future course of events is predicated on (or emerges out of) the interaction between humans, tools and material. As such, the way a material behaves has an influence on the overall behaviour of the creative system.

Enactive Signification: If we see drawing as an explorative act rather than a representative one, then the sense that a drawing gives to us and its materialisation are recursively co-dependent. By this we mean that the meaning of a drawing can be neither separated from the physical act of drawing nor from the specific materiality of pencil and paper. Visual perception is not an information processing task, but a physical sense-making experience in which meaning-making takes place in a sphere that is unmediated by language.

Creative Thinging: In his paper *The Thing*, Heidegger (Heidegger and Hofstadter, 2013) coins the term “thinging” in order to refer to the agency of a non-living entity. By linking “creative” and “thinging,” Malafouris (2014) adapts the term to refer to the activity of an extended mind as it emerges from the relationship between human and material. Although similar, “Creative thinging” is distinct from the term “epistemic action” that we met earlier in that epistemic action refers to a human action whereas creative thinging describes the activity of a transitory creative system (which includes a human). We can understand creative thinging to be a systemic formulation of, thinking-as-doing.

We will now turn to the case-study which will enable us to bring to life the extent to which thinking is shaped by the physical qualities of material. Our aim is to highlight evidence for the concepts of extended mind, enactive signification and material agency and to show how they develop together into the process of creative thinging. The case study is a first-person description by one of the authors, Paul March as he goes about his work as a ceramic artist. The reported action occurred on the same day that Paul March drew up the plan for this chapter: a fact worth knowing because, as will become clear, writing and crafting become inseparably intertwined.

Case Study: How Material Sculpts Thought

I spent the morning making a plan for this chapter and in the afternoon, I went back to working with clay. My first task was to test out a new surface treatment for a sculpture-in-progress. Normally, I would test this by rolling a lump of clay into a rough tile-shape before applying the surface treatment to one side. But as I was about to start I looked across the workshop and my eye caught sight of a small goblet that I had made about a year before. The goblet had also been a test—this time of the material properties of a mixture of paper, flax and clay. Once the test was complete, I had hoped to be able to drink my morning coffee from the goblet but the paper-clay mixture turned out to be porous and so, despite its success as a test, the goblet itself was useless as a functional vessel. But when I glimpsed it again, I realised that its rounded surface offered a better approximation to the form of the present project than a flat tile and so I started work on a second cup.

I began by rolling small pieces of stoneware clay into thin sausage-shapes, with a view to using the coiling method. As the name suggests, the method involves building up the walls of a vessel by spiralling a cylindrical coil of clay onto itself in a circular motion before smoothing down the joint between layers. A more-or-less cylindrical vessel such as a goblet grows naturally from this procedure. When the smoothed clay sides had lost some of their humidity, I held the conical object in my hands with a gesture that was meant to feel and adjust the circularity of the vessel. The clay felt comforting and I imagined sitting at the breakfast table with the cup-to-be full of coffee in my hands. As I did so, I began putting pressure on the clay and the cylindrical form adapted itself into the shape of my palms. I pressed harder and then I relinquished the grip. I enjoyed the vibrancy of the gesture and the impression it made with the clay. With two fingers on the inside of the rim, I re-formed the vessel into a cylinder and then repeated the process. After a couple of rounds of this game it became pretty clear that I was no longer making a cup. I was sculpting a vessel by cupping my hands.

Once it was finished, my next task that afternoon was to test the same surface treatment for another project—this time one that had porcelain as its clay substrate. I am a sculptor and, as I will go on to describe, porcelain does not lend itself to sculpting and so I use it very rarely. I opened a bag of porcelain and touched the sticky clay. As I did so, I realised that the morning plan for this chapter was beginning to change and that what I was about to do would change it further. For the second time that afternoon, I rejected the intention of making a test-tile and began work on sculpting another cupped-vessel. I intended to compare and contrast the influence of porcelain and stoneware on the creative process in order to write about it here.

The plastic qualities of porcelain change very rapidly as water evaporates. Within the space of 15 mins, the clay goes from being super-elastic, like bread dough to brittle, like toast. Gestures that work so well with stoneware are not at all suited to porcelain. Even the tools I normally use feel ill-adapted. I have worked for years with stoneware and I am an expert in its behaviour. In contrast, my lack of experience with porcelain probably contributed to the clumsy work procedure that I could see unfolding before me. The struggle with porcelain brought into stark relief the plastic quality of stoneware that familiarity had rendered invisible to me. Working with stoneware gives me few surprises. My hands move easily between its possibilities and its limitations, whereas porcelain leaves me continually thwarted by the failure of each gestural intention. As I cupped the cylinder of porcelain in my hands, in place of the tight, elastic responsiveness of stoneware, I felt the slack emptiness of those areas that were still wet and the stubborn intransigence of those that had already lost too much water. Unlike the work with stoneware, the encounter with porcelain was a dispiriting experience. As a result, I spent less time on it, not least because, beyond a certain point, the clay simply stopped responding to my gestures, discouraging further gestural reaction and closing down the possibilities of an exploratory relationship.

Figure 1 On the right of the photo, the dark cup is made from stoneware with the porcelain version to its left.

Nine Lessons of Material Change

The image (Fig 1.) of the two unfired vessels, side by side (before the application of the surface treatment for which they were both tests) provides a vivid demonstration of the differential influence of material and of familiarity of material on the process of creation. In addition, this short case study highlights nine specific features of the process of creative crafting.

- 1) The familiar feeling of stoneware and of tools and the automatic recourse to the use of tiles as test samples all indicate the extent to which habitual work practice organises present activity. This undermines the idea of prior intention as a manifestation of a human agency that is determined by the activity of the executive function system (anatomically located within the pre-frontal lobes). It suggests instead that intention arises procedurally, through and within the extension and adaption of ongoing activity. By suggesting this, we do not seek to deny the crucial part played by the brain's pattern of neural activity. What we seek to question is the metaphor that equates the prefrontal lobes with an executive board. If a business metaphor is necessary, that of a cooperative seems more apt.
- 2) A change of clay disrupts habitual gestures, turning an expert tool user into a clumsy one. This illustrates the extent to which gestures, tools and clay, work in concert. To define one of these three elements in the absence of the other two is meaningless. Instead, expert gestures, familiar material and well-adapted tools should be seen to come together to form a temporary unit of cognition—an extended mind that functions through creative thinging.
- 3) A change of clay use, from stoneware to porcelain, reveals the extent to which the familiarity of stoneware has become almost literally incorporated into the bodily awareness of the sculptor. In this way, the division between what is human and what is clay is blurred as a lump of stoneware becomes a prosthetic organ of creative exploration.
- 4) The observation of features in the environment (in this case, noticing a goblet on a shelf) disrupts procedural intention. The emergent new direction is therefore not the result of an ideational change occurring in a virtual, conceptual space but is the next step in an encounter that happens in the real, physical space between a human and non-human entity. The pattern of relationship between the two delineates, once again, an ephemeral extended mind.
- 5) The formation of a cylindrical shape such as a cup emerges easily and naturally from the coiling method of construction—demonstrating that unfolding form, material plasticity and habitual work practice are co-dependent.
- 6) The making of a prototypical cup was disrupted by the agreeable feeling of squeezing the clay form between the palms. In this way, a change in habitual work practice was conceived, not in the head, but through a sensitive engagement with material.
- 7) The repetitive gesture of deforming and reforming the clay cylinder between the palms was described in the case-study as a game, suggesting that a change of intention can be seen as occurring through the uncertain consequences of engaging in play.
- 8) Making the cup and writing this chapter are linked by a transactional relationship. Each is responsible for giving form to the other.
- 9) The concept of a cup as cylindrical container is replaced by the concept of a vessel that is sculpted by the same gesture of the palms that will cradle it later when it is filled with hot coffee. This cognitive transformation does not take place in a virtual conceptual space. The concept emerged through enactive signification—the collaborative engagement with material that has been described through the previous eight points. In this respect, cognition and material activity are indistinguishable. A change in meaning is brought about, not by a linguistic reinterpretation, but by the gesture of holding the clay vessel between the palms and experiencing it both as a cup and as the sculpture of a cup.

Conclusion

The theories and examples offered in this chapter provide evidence of a profound relationship between craft and creativity. This relationship is based on the fact that both creativity and craft are ultimately grounded in the co-participation of person and world in the process of making. We use “making” here in a wide sense that does not exclude thinking; on the contrary, the concept of “creative thinging” brings the two together. In order to describe how creative thinging is exemplified by the context of crafting, we have introduced an ontological shift. Instead of conceiving of creative thinking as taking place exclusively inside the mind, both isolated from and yet somehow influenced by the “outside,” creative thinging happens at the interface between person and world, between self and other, between mind and matter. This paradigm change towards the notion of “making” as a process of engagement with material, society and the world of culture is long overdue in creativity research and it is by exploring unconventional topics like craft that this encyclopaedia encourages us to challenge a series of implicit assumptions about the nature of creativity.

The practice of craft and the process of creativity are thereby inseparably intertwined. In contrast, the historical separation of art from craft that we have highlighted reflects a schism between, what is known as “little” and “big” creativity. On the big side, the revolutionary creations of the artist or innovator, shape his/her field allowing him/her to leave a mark on society. By definition, big creativity is highly visible. On the little side, the process of creative expression that continuously develops, builds and maintains human culture and society either goes unnoticed or is viewed as mundane. Today we live in an age in which crafts are being rediscovered and are gaining a new appreciation. Perhaps we can take this as a sign that society is beginning to reconsider creativity as something more democratic, participative, and therefore more accessible to all.

Introduction

Creativity, according to *Webster's*, is “the ability to create new meaningful forms.” [Dean Simonton \(2000\)](#) described it as the ability to create something useful, that works and is non-obvious or, as he succinctly puts it, is the “conjunction of novelty, utility and surprise”. In his landmark book *The Lever of Riches* (1992), a sweeping study of technological creativity from classical antiquity through the Industrial Revolution the economic historian Joel Mokyr put creativity in a Promethean frame:

Economists and historians alike realize that there is a deep difference between *homo economicus* and *homo creativus*. One makes the most of what nature permits him to have. The other rebels against nature's dictates. Technological creativity, like all creativity, is an act of rebellion. (p. viii)

Yet creativity is not the exclusive province of a few select geniuses who can get away with breaking the mold because they possess superhuman talents. It is a capacity that everyone possess, to varying degrees.

Creativity has become a key driver of the Creative Economy. The old Industrial Economy which was powered by raw materials and physical labor has been supplanted by a new Creative Economy powered by knowledge, innovation, and human creativity. This Creative Economy is composed of Creative Industries which span sectors from science and high-tech, research and knowledge industries, to media, music, design, and the arts. This new Creative Economy is the principal driver of innovation, jobs, and economic growth in the advanced nations today.

Capitalism has expanded its reach to capture the talents of eccentrics and nonconformists who would once have been viewed as bizarre mavericks operating at the bohemian fringe, placing them at the very heart of the process of innovation and economic growth. These changes in the economy and in the workplace have in turn helped propagate and legitimize similar changes in society at large. The creative individual is no longer viewed as an iconoclast; he or she is the new mainstream. Indeed, the growing ranks of creatives are part of a new and rapidly expanding class of workers the Creative Class, who work in science and technology, knowledge work and the professions, arts, design and media, and who make up anywhere from a third to a half of the workforce in the advanced nations.

Creativity has come to be the most highly prized commodity in the economy—and yet it is not a commodity. Creativity is an attribute of people and as such it annihilates the social categories of gender, race, ethnicity, and sexual preference. Today's Creative Economy requires diversity, because every single human being is creative and can potentially contribute to it. And while people can be hired and fired, their creative capacity cannot be bought and sold, or turned on and off at will. So, the workplaces have changed and continues to evolve. Schedules, rules and dress codes have become more flexible to cater to how the creative process works.

This entry discusses the rise of the creative class, the creative economy, and creative cities, and the opportunities and challenges they pose for modern society.

Creative Industries and the Creative Economy

Creativity has become the key factor in the economy. In virtually every industry, from automobiles to fashion, food products to information technology, the long run winners are those who can create and keep creating. This has always been true, from the days of the Agricultural Revolution to the Industrial Revolution. But in the past few decades, the business community has come to recognize it clearly and act upon it systematically.

It's become commonplace to say that this is an “information” or a “knowledge” economy ([Machlup, 1962](#); [Bell, 1973](#); [Drucker, 1995](#)). But, what's more fundamentally true is that the economy is powered by creativity. Both at work and in other spheres of life,

creativity is, creativity is more highly valued and cultivated more intensely than ever. The creative impulse—the attribute that distinguishes humans, from all other species—is now being unleashed on an unprecedented scale.

John Howkins (2002) was among the first to use the term “creative economy.” In his 2001 book *The Creative Economy*, he identified fifteen key creative industries, including software, R&D and design, and creative-content industries like film and music. These industries produce intellectual property in the form of patents, copyrights, trademarks, and proprietary designs.

But it would be a mistake to suppose, that creativity can be reduced simply to the creation of new blockbuster inventions, products, and firms. In today’s economy, creativity is pervasive and ongoing: it drives the incremental improvements in products and processes that keep them viable just as much as it does their invention. Moreover, technological and economic creativity are nurtured by and interact with artistic and cultural creativity.

The growing salience of the Creative Economy is powered by the rise of Creative Industries. The share of overall employment in these industries which span high-technology, knowledge work, and arts, culture design, and media has grown significantly in the past couple of decades, and entirely new creative sectors such as computer graphics to digital music and animation have emerged. Meanwhile, economic activity in traditional manufacturing industries has shrunk as a share of overall activity as traditional production has either gone offshore or become more reliant on automation. Over the past several decades, the economies of the advanced nations have shifted from industrial to Creative Economies.

The shift to the Creative Economy and Creative Industries entails three big economic shifts (Caves, 2000; Scott, 2014; Menger, 2014). First, the products and services of the Creative Economy are more tailored to the subjective tastes of the consumer: which books, music, movies or games will succeed in market are hard to know in advance. It is very hard to know or predict what will be a “hit” in advance. For this reason, the Creative Industries face great uncertainty. Second, the Creative Industries tend to rely on the Internet and digital forms of dissemination. That means once these creative products are produced it costs very little to distribute them. Third, the Creative Economy takes the form of a winner-take-all economy, where film and music superstars garner a disproportionate share of rewards.

Creative workers, as Peter Drucker (2012) long ago pointed out, cannot be motivated merely by money, but seek intrinsic rewards that come from working on interesting and challenging projects with interesting colleagues and collaborators in comfortable flexible surroundings on their own with flexible schedules. As Drucker pointed out, rather than being treated as conventional employees, knowledge or creative workers must be treated more like volunteers whose commitment to the organization or company is contingent, and derived not from their pay or monetary rewards but from the challenge of their mission and the nature of the work itself.

This has given rise to sweeping changes in the workplace. These include new organization forms and workplace designs which seek to nurture and harness creativity. It is visible in new more loft-like office designs which emulate artists’ studios, more flexible schedules which morph work and leisure, and more casual dress codes. Creativity cannot be “forced” out of workers and does not march to the strictures of scientific management or the industrial assembly-line. And new structures have emerged to cultivate it. These include the ascendance of onsite employee amenities like catered meals and recreational facilities, and also the rise of new co-working spaces as other organizational forms of the so-called sharing economy, which allow for freelance workers to realize benefits of specialization that were previously only available within a firm.

The Creative Class

The economic need for creativity has registered itself in the rise of a new class, which we call the creative class (Florida, 2014). Its members’ economic function is to create new ideas, new technologies, and/or new creative content, and they work in fields such as science and engineering, architecture and design, education, arts, music and entertainment. Around this core, the creative class also includes a broader group of *creative professionals* in business and finance, law, health care and related fields. These people engage in complex problem solving that requires a great deal of independent judgment and high levels of education. But membership in the creative class is not simply a function of educational attainment. Some of the creative class’s most archetypal members, like Steve Jobs and Bill Gates, Andy Warhol and Jimi Hendrix, did not have college degrees. Across the entire United States, nearly three-quarters of adults with college degrees are members of the creative class, but less than 60% of the creative class holds college degrees. But whether they are artists or engineers, musicians or entrepreneurs, PhDs or dropouts, what all members of the creative class share is a common ethos that values creativity, individuality, difference, and merit.

The key difference between the creative class and other classes lies in what they are paid to do. Those in the blue-collar working class and the service class are paid to do routine work, while those in the Creative Class are paid to use their minds – their cognitive and social skills.

The creative class has expanded dramatically in recent years. In 1800, it accounted for roughly ten percent of the US workforce, and it hovered between that and 15% until 1960. It increased gradually to almost a fifth of the workforce in 1970, to about a quarter of it in 1980, and with more than 40 million members, comprises about a third of it by the 2010s. Countries like Singapore, the Netherlands, and Switzerland have even higher creative class shares, between 45 and 50% of their workforces. And the shares are even higher in leading creative cities, like San Francisco, London, and Berlin.

Creative Cities

The history of human creativity and of human progress is in large part the story of creative cities. The Epic of Gilgamesh—perhaps the oldest known work of literature—closes with an awed description of the walls of the city of Uruk. Plato's *Republic*—which envisioned an ideal city—was a product of the cultural and intellectual flowering of the earthly city of Athens, as well as a broadside against its politics. Dante, Petrarch, Boccaccio, Brunelleschi, da Vinci, and Michelangelo all were born in or near the city of Florence. Great thinkers, artists, and entrepreneurs rarely come out of nowhere. They cluster and thrive in places which attract other creative people, and that provide environments that foster and support creative efforts.

Cities have long functioned as critical containers and mobilizers of creativity, attracting creative people from the surrounding countryside, while providing the structures, scenes and ecosystems which undergird and support creative effort. As the great Swedish economic geographer Ake Andersson (2001) a leading student of creativity and cities, put it: "Creative people need creative cities." Andersson noted the flourishing of creativity in four different cities from four very different eras: Athens circa 400 BC, Renaissance Florence, Enlightenment London and *Fin de Siècle* Vienna. One could add New York City and Silicon Valley and numerous others in the present era: He stated that, "The creative city as an informal and spontaneously evolving spatial organization has been the arena for all large-scale creative revolutions," (Andersson, P. 39) Andersson added: "In the course of the past 2500 years, a small number of relatively large cities have functioned as hotbeds of revolutionary creativity. These cities attracted a disproportionate share of migrants with creative inclinations, and they also facilitated the growth of creativity among those already present. Such cities were both used as arenas for presenting findings from elsewhere and as fertile locations for developing new ideas in collaboration with other creative people."

Even deeper in our past, the congregation of populations into progressively larger, denser, and less isolated groups may have been the prerequisite for humanity's further evolution. Archaeologists and anthropologists noted evidence of a flowering of artistic and material creativity that occurred roughly 40,000 years ago in Europe, reflected in everything from cave paintings, figurines, and jewelry, to the complex tools that allowed farmers to begin actively transforming nature. Some scientists attribute this leap to advances in cognition and memory. But pioneering studies by archaeologists and anthropologists put communities—not genes—at the center of this evolutionary watershed (see, Boyd et al 2009; Shennan, 2009). Their research described how the earliest leaps in human development occurred in early city-like formations, places where populations were growing denser, larger, and more clustered. Those leaps were products of people working and thinking together. Many of these cultural and artistic blooms withered when populations shrank, and communities unraveled. This research found close relationships between advances in toolmaking and population size. As people gathered into larger groups and came into contact with one another more frequently, knowledge was shared, retained, and advanced more easily.

Cities do more than just attract creative people and provide a broad environment or ecosystem for creativity; they stimulate it as well. They do this in two key ways, according to Simonton. For one, cities play a critical role in creative development. Creators need to be exposed to role models and mentors during their adolescence and young adulthoods. This is something that is much more likely to occur in cities, where more role models and mentors are likely to be available and where people are pushed closer together. And, talented and creative people, especially those who are high in openness-to-experience – the personality trait most associated with creativity – are much more likely than others to cluster in dense, diverse cities (Rentfrow, 2011).

Creativity is a product of diversity and diverse communities; it requires the cultural heterogeneity that is the hallmark of big cities (Page, 2010). Research found a close connection between the concentration of artistic bohemians and of gays and lesbians in a community and its levels of creativity and innovation (Florida, 2014). It is not that the bohemian or gay community is more technologically innovative than others. Rather, higher concentrations of bohemians and gays reflects a greater underlying openness to the diversity and cultural mixing that attracts innovators and entrepreneurs, and thus propels innovative activity. As Simonton put it: "It goes without saying that an urban environment will afford a more diverse variety of potential priming stimuli than will a rural environment. The former, relative to the latter, is more likely to offer a world replete with different languages, cultures, religions and lifestyles," adding that: "The more urban the setting, the more diverse and hence more creative such a group is likely to be."

Creative Contradictions

But the rise of the creative economy and of the creative class also poses challenges for society and economy. Creative class workers today bear much more risk than the corporate and working classes of the old Industrial Age – as became all-too-obvious at the height of the economic crisis in 2008 and 2009. Stress levels too are high. The technologies that were supposed to liberate workers has invaded their lives.

The rise of the creative economy and of the creative class also led to deep social, economic, and political divides. Society is sorted and segmented by levels of education, the kinds of work people do, and where they live, and this in turn shapes ever more divisive culture wars and politics.

One of the most significant fault lines of the current age is the growing geographic segregation of the classes. Places where the creative class is more concentrated are economic winners: they have stronger economies, higher levels of income, and higher levels of economic growth. They are also more likely to vote for liberal politicians, which heightens partisan divisions.

Different kinds of people have always sorted themselves into different kinds of neighborhoods. Little Italy's, Germantown's, Harlem's, and other ethnic and racial enclaves have always been a feature of cities, as have artistic and cultural centers like New York's Greenwich Village. For better and for worse, college towns like Madison and Boulder have distinctive personalities and qualities of life, as do former manufacturing towns like Pittsburgh and Detroit. But the divisions between and within cities and regions – crossing urban, suburban and rural lines – have deepened with the rise of the creative economy. The economic and social geography have morphed into a veritable patchwork, with small spans of concentrated advantage juxtaposed against much larger swaths of concentrated disadvantage.

There are increasingly global divides too. People everywhere increasingly eat the same foods, wear the same kinds of clothing, and consume the same kinds of music and entertainment, no matter where in the world they live. This has in some ways made the world smaller and brought its economies and peoples closer together. But instead of reducing and flattening economic and class distinctions, it has made them sharper. The creative class in urban centers like London, Paris, Berlin, Stockholm, New York, Los Angeles, Toronto, Sydney, Tokyo, Shanghai, Singapore, Bangalore, Tel Aviv, Mexico City and Sao Paulo have far more in common with each other than with the working classes of their own countries. The defining feature of the creative economy is that it is winner-take-all and thus spiky – and it is getting spikier and more divided all the time. These worsening class divisions are at the heart of the populist backlash—the angry, backward-looking nationalistic politics that are on the rise around the world.

The rise of the creative economy also exacerbated global economic instability. Though the immediate occasion for the crash of 2008 was the bursting of the real estate bubble, in larger terms, it was the transitional crisis of the old economic order—the death spasm of an outmoded, exhausted system, and the birth pangs of a new one. The rise of the creative economy should be seen as a fundamental, epochal transformation, like the shift from agrarian feudalism to industrial capitalism, which was also accompanied by earth-shattering religious, political, intellectual, and social upheavals. The current moment has much in common with the Long Depression of 1873, which coincided with the rise of modern industry, and the Great Depression of 1930s, which followed the rise of mass production capitalism. This is the dawn of a new social and economic order.

Despite its instability, there are reasons for considerable optimism. In the new creative age, the most valuable economic attribute is not land or capital but creativity—an endowment that every human being shares in. For the first time in history, the logic of economic growth requires the fuller development and flourishing of human potential. This disruption is frightening, and the dangers of backsliding and civilizational atavism are real. But society is hopefully standing on the threshold of a much richer and more humane epoch.

Origin of Creative Destruction

Creative destruction is a macroeconomic term describing the process “that incessantly revolutionizes the economic structure from within, incessantly destroying the old one, incessantly creating a new one.” (Schumpeter, 1942, p. 83). Schumpeter popularized the term to describe a force metaphorically labeled ‘industrial mutation’. Similar to its biological counterpart, he described a process of permanent alteration and implied that it is similarly unplanned, unintended, and unpredictable. Schumpeter uses creative destruction to describe the force that allows new actors to rapidly enter an existing market and establish themselves in addition or instead of existing companies. Schumpeter observed that the introduced changes must be radical enough to impact the existing market, since the existing structures have a considerable market force. As established players, the market force is used to keep the status quo, or incrementally improve their position. If the new participants succeed with their radical change, established agents suffer a devaluation and will ultimately be destroyed. This destruction is a necessity for the next iteration of the business cycle.

Radical creative destruction was described as stepwise and cyclic, with revolutionary phases of renewal and destruction intertwined with phases of tranquility. According to Schumpeter, all these phases are part of the same process: either revolutionary replacements of existing structures or the implementation and absorption of change. Cyclic repetitions of these phases lead to long-term economic growth of the whole market. Since the renewing forces come from within, this process does not change the underlying system. Nevertheless, Schumpeter claimed that at some point these cycles create the conditions for the self-destruction of the system. However, for the capitalistic system he described, this has not yet happened in the predicted form and time.

The Historic Context of Creative Destruction

Schumpeter was not the first to develop the idea or the term of creative destruction. For example, Karl Marx had previously described a similar process without using the term. Marx had argued that an eventual self-destruction of the system through these destructive forces would be inevitable.

Werner Sombart also described a similar process in his early works. In the conclusion of his book on “War and Capitalism” (“Krieg Und Kapitalismus”), Sombart drew a connection between the deforestation of Europe, the rise of capitalism, and war as a force of creative destruction. In short, he stated that war created a demand for ships, which led to a shortage of wood. This deficit in turn created the need for alternative burning material and the development of metallurgical coal. As this was the inaugural moment for the steel industry, he suggested that the destruction (e.g. of forests) caused by war led to the creation of capitalism. Poetically, he summarized this: “In turn, a new creative spirit rises from the destruction” (orig.: “Wiederum aber steigt aus der Zerstörung neuer schöpferischer Geist empor”, Sombart, 1913, p. 207). This is particularly interesting as Sombart published this book on war as the enabler of capitalism just before the First World War was about to begin.

Marx and Sombart described the creative force of destruction as positive and, to some extent, inevitable. It seems that Schumpeter agreed with Marx and Sombart. However, taking their interpretation a step further, he suggested that the destruction of existing

structures is necessary and a positive contribution to the long-term growth of the whole system. It is Schumpeter who then explicitly popularized the technical term 'creative destruction' for a wider audience.

Theoretical Observations About Creative Destruction

Destruction and Creative Destruction

Destruction can be summarized as "damage beyond recovery or repair, changing something into a state of non-existence" (See Destruction and Creativity). This definition implies that the destructive force has no intention of creating something out of what it has destroyed. Moreover, destruction does not require a preceding constructive or creative process and does not refer to one artefact being replaced by a successor. Furthermore, while creative destruction is a cyclical process, a destruction is a one-off event.

Creativity and Creative Destruction

The extent of this Encyclopedia bears witness to the fact that creativity is a multifaceted and complex phenomenon. Nevertheless, there is some agreement to summarize it as the product of novelty and usefulness, possibly with an element of surprise in it. Creative destruction, generalized from the term introduced by Schumpeter (1942), similarly refers to a revolution through renewal, to a novel element replacing an existing one. To achieve this, the novelty has to be useful with considerable more value than existing solutions. These useful revolutions in creative destruction resemble qualities similar to the 'standard definition of creativity' (See Definitions of Creativity, Novelty). Furthermore, Schumpeter suggested that creative destruction is unpredictable in its timing and needs a quick implementation. It shares its suddenness with the notion of surprise that scholars like Margaret Boden attribute to creativity itself. Therefore, both concepts exhibit a great conceptual overlap with each other (See Novelty).

On the other hand, creative destruction refers specifically to a process or action. Other aspects of creativity have defined roles, at least within the economic system. Referring to the terminology suggested in Glăveanu's (2013) five-A framework for creativity, entrepreneurs would be the creative actors. Consequently, their product is the creative artefact, economic demand is the creative affordance, and consumers represent the creative audience. Similar to how the different aspects of creativity are intertwined, creative destruction relates to these elements but is, nevertheless, a distinctive sub-factor of creativity.

Consequently, creative destruction exhibits greater similarity to the creative action or process than to the overarching term of creativity itself. Drawing on the self-observations from early eminent scientists such as Hermann von Helmholtz and Henri Poincaré, Graham Wallas described the creative process as sequential, with five distinct stages. This model inspired a multitude of similar models, yet they do not cover how one creative process influences the next action. In contrast, a description of an iterative and full cycle of creation is the central concept of creative destruction. In addition to the sequential models of creativity, iteration plays a role in 'design thinking'. For this set of models, and based on the observation of creative practitioners, the economist Herbert A. Simon proposed that prospective problem solvers iterate through several phases such as 'define, research, ideate, prototype, choose, implement, learn' until they find a satisfying solution. This creative model shares its cyclic and iterative conceptualization with creative destruction, but it lacks a clear leap or shift at any transition from one phase to another, which defines creative destruction.

In summary and on a fundamental level, creative destruction is a process but therefore only one of the aspects covered by the term creativity. However, there is great conceptual overlap between novelty, usefulness, and even surprise as possible factors both for creative destruction and creativity. Moreover, neither the sequential model of creativity nor design thinking refer to destruction, either directly or indirectly (See Design Thinking and Surprise).

Innovation and Creative Destruction

The examples in previous sections demonstrate that creative destruction is often initiated by innovation. In fact, the revolutionary part of creative destruction is often depicted as a reordering of the productive process and goes back to the definition of creative destruction used by Schumpeter (1942). Innovation, outside the economical definition, is any technologically-backed novelty (Schneider, 2017), which does not necessarily end up causing a destruction. Under this point of view, history is full of examples of products that were innovative but did not replace existing ones.

Fundraising platforms such as Indiegogo and Kickstarter contain many brilliant innovations. The role of these platforms within the capitalistic economic system is to increase the reach of small innovators to accelerate their speed of reaching potential consumers. These fundraising platforms are promoters not only of the innovations, but also of creative destruction as a viable and important part of the system. Some of the most successful innovations on these platforms include a smart watch produced by a small startup company. With the help of the platform, it created enough impact to overcome the market dominance of existing watch companies. By now, smart watches are established products from computer and electronic gadget companies rather than traditional watchmakers.

At the same time, these platforms show a variety of innovations that did not even make it past the funding stage. These failures can also serve as examples for future innovators and cycles of creative destruction. Even large companies learned the hard way that innovation is not the only driver of creative destruction if the public is not ready. For example, global players built devices such as smart glasses with built-in cameras and head-mounted displays to augment people's surroundings. While these products failed,

their development led to an increased awareness of privacy issues. Thus, while every creative destruction process starts with an Innovation, not all Innovations become creative destructions. Moreover, the outcome of a development triggered by innovation within the circle of creative destruction is not predictable.

Occurrences of Creative Destruction

Economics

"Creative destruction" was introduced as a macroeconomic term with particular relevance for sociology, national, and international economics. This is evident from the use in Sombart's work and even from how it was popularized by Schumpeter (1942; p. 83): "This process of creative destruction is the essential fact about capitalism."

The fundamental idea is that markets are systems which undergo a continuous process of change, with phases of revolution followed by the assembly of these revolutions. Not dissimilarly from the biological evolution of species, and borrowing some of its terminology, markets continuously 'adapt' and 'mutate' based on 'environmental pressure' as new technologies, goods, and services become available. Just like for the individual creature, this inevitably means that older industries are swept away by ones with better 'fitness' for the changing market. For example, the car industry made manufacturers of horse-drawn carriages obsolete, and the computer industry replaced the manufacturers of typewriters. The creation and destruction of industries are paralleled in the job market and the development of professions and traits. While creative destruction hinders job security in the long run, the labor force migrates between different markets. Consequently, new industries create new jobs and professions along with the need for the adaptation of the national educational system. This example provides a glimpse into how creative destruction operates on a national or even international level and is part of the macroeconomic system.

Likewise, processes similar to creative destruction can be observed in microeconomic decisions. One interesting example comes from the development of the music recording industry during the past decades. Through the innovation of the phonograph, which led to the development of phonographic cylinders and the phonograph record known as vinyl, a demand for recorded music developed on a macroeconomic level in the early 20th century. While the music industry initially sold 78 rpm shellac and vinyl, the invention of the reel and later the cassette tape imparted a blow to the vinyl-related factories. The cassette was later replaced by the compact disc (CD), and the CD by streaming media. Often these technological changes were introduced by companies new to the market. For example, the compact cassette was introduced by Philips, which until then had been a manufacturer of radios, TVs, and shavers. The transition to streaming media is interesting, as the technology of peer-2-peer networks such as Napster was developed without a commercial interest, but still replaced existing music distribution systems through a 'revolution'. In the following adaptation phase, the commercialized streaming media almost entirely replaced the digital CD. As a result, many new recordings are now either released online or as analogue media. Interestingly, these are now often vinyl recordings or even cassette tapes, thus resembling earlier iterations in the cycle of creative destruction.

The process of creative destruction means that industries can never afford to remain stagnant, since competition will otherwise destroy them as progress advances. As Schumpeter (p. 82) wrote, "The fundamental impulse that sets and keeps the capitalist engine in motion comes from the new consumers' goods, the new methods of production or transportation, the new markets, the new forms of industrial organization that capitalist enterprise creates." Under this view, stability, such as that advocated by equilibrium theorists, is not the optimal goal. Rather, constant turmoil and incessant changes in the status quo are to be sought in order to ensure progress and evolution. In this world, entrepreneurs are the catalysts of the change, and in a literal sense the real creative market participants.

Creative Destruction and Society

Human history has seen many destructions and reconstructions of societies, civilizations, and communities. Natural disasters and man-made destructions such as wars may completely change the features of a certain part of the world, yet people's resilience, combined with technological innovation, often result in new settlements being born from the ashes of previous ones. As Sombart argued, this particular aspect of creative destruction is at the core of the capitalistic society (See War).

The destruction of cities can be discussed through the lens of creative destruction as well. Take London and its well documented fires, for example. Early fires happened during Boudica's Revolt in CE 60, others are known as the Hadrianic fire in CE 122. Each time, the city was rebuilt and changed its structure and architecture. With the fire in 675, these changes started to have a less immediate and long lasting influence: some of the major buildings previously made from wood were replaced with stone buildings. This became part of the official regulations after the 'Great Fire of London', when the 1667 Rebuilding Act only allowed new structures to be made from brick and stones. Looking at the fires and the destruction of the city itself, the order of the destruction (fire) and creation (rebuild) seems reversed as compared to the definition of creative destruction. Nevertheless, considering the typical London architecture consisting of residential squares, this was a phenomenon that had started just before the fire and only became the dominant architectural style after large areas were to be rebuilt in a short amount of time after the fire. Here the destruction was not a consequence of a new invention, nor was it triggered by it. Instead, a novel design had already been ideated, and the innovation was waiting to be implemented as an alternative to rebuilding previously existing structures. Even though the rebuild happened before capitalism, which Schumpeter names as a precondition for creative destruction, the development of residential squares within the mercantilist society resembles aspects like the concentration of capital to generate more profit.

Similarly, while creative destruction in economics terms is specifically created by the competitive nature of entrepreneurs, natural disasters happen without the intention to compete with existing solutions. Nevertheless, and like the Great Fire of London, they can exhibit comparable phenomena. Talking about less destructive relationships between a community and its environment, in disciplines such as Environmental Sciences, Tourism, and Architecture, creative destruction entails a specific meaning closely related to the original definition from macroeconomics.

Creative destruction describes the process through which underdeveloped areas undergo a process of restructuring, in order to make their heritage appealing, and increase tourism. According to Mitchell (1998), there are five stages in this creative destruction process: “early commodification”, “advanced commodification”, “early-destruction”, “advanced destruction”, and “post-destruction”.

In the first stage, actors such as local businesses and governments create a market for tourists, for example by promoting a local historical site in an ‘idyllic landscape’. This stage is generally well received by the local population, as new tourists bring money to the community. In the second stage, what had been initiated in the first stage is amplified, with more and more local businesses joining in opening restaurants, hotels, and souvenir shops, and with the local government giving more weight to the tourism and hospitality industries. While all the actors involved in this process benefit from this stage, those who are not involved, for example residents who are not working in the industry, start feeling that the atmosphere of the community is changing, and it is no longer an ‘idyllic landscape’. In the third stage, more and more businesses are created to meet the demand from visitors, and this includes business that do not represent the historical or cultural value of the place, such as fast food restaurants and shopping malls. A growing number of residents develop negative attitudes towards this change. In the fourth stage, residents either resign themselves to the disruption brought in by the businesses, and try to partake in their benefits, or relocate. At this point, if left free to operate, disruptions will be major, such as the construction of big shopping and amusement centers completely changing the atmosphere of what once was an ‘idyllic landscape’. Finally, during the post-destruction stage, the place might find a new equilibrium, either by completely changing its outlook, or by partially going back to a less touristy destination.

While in economics, creative destruction often has an immediate impact on lives through the change of job specifications and locations of manufacturing – people are forced to change their profession or follow the work by moving to different locations – in the tourism industry the five-stage process described above implies less direct changes, as people’s wellbeing is impacted in other ways.

Creative destruction describes the process of the continuously changing economics and society. As a result of these changes, some industries and individuals will be better off, while others will lose – job, societal relevance, or useful knowledge. In its extension, this makes the moral dilemma of creative destruction visible: Should individuals develop and introduce innovations, knowing that new industries and professions will be created at the cost of making existing industries and jobs obsolete? Should society welcome electric cars as individual transportation as they shift production from one market segment and one location to another? Should people keep allowing artificial intelligence into manufacturing, online retail websites, academia, and other industries, knowing that they will solve problems faster and more efficiently, but will replace human workers? Is it even possible to change the course of creative destruction once it has begun?

Natural Sciences and Theory of Science

A new scientific truth does not triumph by convincing its opponents and making them see the light, but rather because its opponents eventually die, and a new generation grows up that is familiar with it. Max Planck (translated in “Scientific Autobiography and Other Papers”, trans. F. Gaynor (New York, 1949), pp. 33–34); paraphrased as “Science advances one funeral at a time”

Science has been dotted by what have been called “Scientific revolutions”, that have either changed the way humans understand the world, or at the very least made life a little bit easier. Discoveries, include the description of the Solar System by Copernicus, the introduction of the number 0, or the discovery of wave-particle dualism; technology-based revolutions, improved daily life with transportation on wheels, mobile phones, and ball pens. The creative destructivity of these revolutions – the paradigm shifts, mentioned earlier – describes how previously accepted paradigms are superseded by their successors. For example, Copernicus placing the sun in the centre of the solar system replaced the geocentric model.

The geocentric model of the solar system assumed that the Earth was at the centre of the universe. Developed over many centuries by astronomers like Ptolemy, a sophisticated system with pre-calculated tables and catalogues of star formations predicted the position of the sun and moon. This scientific model was continuously improved and was precise in predicting the seasons for farmers and in aiding the navigation of travellers. Then, the heliocentric model was rediscovered and introduced to Europe by Copernicus in the 16th century. Similar to previous heliocentric models by scholar in ancient Greece, and following observations by Brahe, Kepler then formulated three laws that described the ellipsoid movements of planets. Galilei’s observations and Newton’s description of the laws of gravity finalized the creative destruction of the geocentric model, which was completely replaced by the heliocentric model.

Thomas Kuhn, who studied theory of science and who proposed the idea of ‘paradigm shifts’ in his 1962 book, had previously published ‘The Copernican Revolution’ in 1957. Kuhn, a Physics graduate who was mentored by a later Nobel laureate, was intrigued by the changes that led to the development of different fields within modern physics. Replacing the classical Newtonian mechanics, models proposed by Skłodowska-Curie, Einstein, Planck, and their contemporaries, revolutionized the understanding of nature. Their observations across the different disciplines in the natural sciences often replaced previously established models within a short time. Kuhn used these examples in his book to illustrate how new theories in continuously replace previously

accepted ones. Since its publication, new discoveries, such as the confirmation of the existence of the Higgs boson, have shown how a model similar to that of creative destruction can be applied to the natural sciences.

According to Thomas Kuhn, every field of scientific research undergoes the same cycle, now known as the Kuhn cycle: the tranquillity of day-to-day scientific problem solving activity, dubbed 'normal science', is troubled by more and more occurrences of the current paradigm not being able to solve problems. At this point, in a so-called "paradigm shift", a new paradigm is created, replacing the existing one. Within this newly created paradigm, 'normal science' can flourish again, 'solving puzzles' set out by the paradigm and using the methodology of the paradigm. Interestingly, the introduction of Kuhn's cycle was a paradigm shift in itself, especially in the fields of history and philosophy of science. Previously, the proponents of the old rationalist paradigm, with theorists such as Karl Popper, understood scientific progress as a continuous accumulation of falsifiable theories and ideas. Following the idea introduced by Kuhn, there are no more steady steps, but leaps between scientific paradigms. In its ultimate consequence, the Kuhn cycle predicts a replacement of itself, once too many conflicting observations have been accumulated. Interestingly, Kuhn shares this notion of self-destruction with Schumpeter's description of creative destruction.

It is worth noting that Kuhn's ideas of paradigms and revolutionary changes in science have been met with skepticism. A justification or even a summary of these arguments would exceed the current entry and is given elsewhere (e.g. Bird, 2001). Nevertheless, the idea of paradigm shifts in science has been around for almost 60 years and has since been used to describe progress in academia; it has also entered the English language as an idiom. Consequently, it is difficult to follow or even estimate the direct influence that Kuhn's writing has had on the scientific community without considering his influence on the popular culture.

Policy-Making

One of the drives of creative destruction is competition: entities need to keep reinventing themselves, or they face destruction. The same process can be observed in political institutions, where, for example, policies and regulations are written and dismissed to follow the pace of modern thinking.

The need for new policies is driven by phenomena such as innovation and change in socio-cultural sensitivity. For example, a growing environmental awareness in the past decades has led to an increasing number of policies for sustainability transition being created, both within and between nations (see e.g. Kivimaa and Kern, 2016). These range from local councils traffic bans to national plastic bag levies, to worldwide agreements to reduce carbon emissions. The apparent losers, in an economic sense, are entities such as plastic and car manufacturers, that need to reinvent themselves in order to continue to survive. What is more, there are scholars, such as Kivimaa and Kern, who argue that all policies that work towards a transition of some kind need to incorporate both elements of creation and destruction in order to be effective.

Arts and Media

The history of Art has also seen waves of new, revolutionary movements, such as Mannerism, Impressionism, and Cubism. Many of these movements corresponded to points in time where changes were already happening at the political, societal or technological level. In fact, philosophers like Wolfram Bergander argue that destructivity needs to be part of any work of art, and Pablo Picasso is also quoted to have said that painting is a "sum of destructions". Interestingly, while creative destruction in scientific terms can become evident rather early during the destruction phase – e.g. when a new scientific discovery is made – artistic movements and indeed artistic genius are often recognized as such in hindsight, when the movement has already had its peak or the genius is dead.

In the media, another recent example of an innovation that is destroying industries that are not adapting to this newly set standard is the rise of on-demand video-streaming as opposed to TV broadcasts: as of 2019, around 50% of US American people have chosen this kind of entertainment industry, while old-fashioned cable TV companies are steadily losing shares and video renting services are almost obsolete in the US: Netflix was one of the causes of Blockbuster's bankruptcy in 2010. This phenomenon is so evident that the phrase "Netflix effect" has been coined to indicate this type of creative destruction.

Finally, talking about popular Art, there is a video game inspired by creative destruction: <https://www.creative-destruction.com/>. Every element in this game can be destroyed and transformed into building materials with a special weapon called "Destructor". It is therefore possible to experience a full destruction-creation cycle while sitting comfortably at a computer!

Cultural References

In Hinduism, the idea of cyclic 'creative destruction' refers to the cosmological realm occupied by Shiva, whose continuous dance of creation and destruction governs the universe. There, the concept of creative destruction is also a never-ending cycle: Brahma, the builder, creates the universe; Vishnu, the preserver, takes care of the created, and Shiva, the destroyer, destroys it, so that Brahma can build it again. In other traditions within Hinduism, Shiva is also called Shiva Nataraja, the Lord of the Dance, and he is both the creator and the destroyer. As Reinert and Reinert (2006, p.59) put it: "His dance is the dance of the universe as it endlessly moves from creation to destruction, destruction to creation. It is in his nature to embody both, as one is not possible without the other."

Another cultural reference for creative destruction comes from ancient Greece. In these legends, the mythological bird phoenix rises from its own ashes. A long life and often death through incineration are part of the motif. This creation-destruction-creation cycle is a symbol of regeneration and renewal. Just like the process of creative destruction, it is never-ending. For the phoenix it is

also not clear where the cycle starts: does the creation follow the destruction, the destruction the creation, or is it a three-step process consisting of creation-destruction-creation or destruction-creation-destruction? The myth of the phoenix is therefore an interesting way of asking the question “what came first, the chicken or the egg”.

Such cycles of life, death and regeneration are sometimes considered allegories for eternal life. For example, by associating the phoenix with the repeatedly burned city of Rome, the Latin poet Martial alluded to Tibullus’s notion of Rome as the “Eternal City.” However, the cycles of creative destruction are neither rhythmical nor eternal.

Conclusion

This entry followed the historic and conceptual origins of creative destruction and provided a theoretical evaluation in the context of creativity. In particular, this entry focused on early descriptions of the principle by Marx and Darwin’s biological evolution, and at the popularization of the term ‘creative destruction’ by Schumpeter. The entry further illustrated the underlying principle by referencing similar ideas expressed in science and culture, from paradigm shift to the mythological bird phoenix.

By taking a step back, this entry discussed the theoretical relationship between creative destruction and creativity. In particular, the role of innovation as a trigger for disruptive changes leading to creative destruction posed a question that every reader might want to consider for themselves. Triggered by innovation, creative destruction propels a novel and useful idea into the market, and, at the same time, necessarily destroys an existing one. In current day societies, each established market participant is interlocked with the fate of employees, their families, and their communities.

If you held the key to such an innovation, would you deploy it for the benefit of the new idea and accept the destruction of others? Or to put it differently using a final example: There are thought experiments exploring the moral dilemma of steering your car to kill one person to save five others (Awad et al., 2018). Taking this example to the macroeconomic scale: Assume that technological development is inevitably replacing one car manufacturer in the near future. If you had the knowledge to significantly improve the next generation of individual transportation, would you share this and therefore accept the subsequent destruction of five existing car companies instead?

Glossary

Audiences People who come in contact with the new ideas, pieces of art, literature, technology and science produced by creative agents.

Autonomously Creative People People such as artists, designers, garage inventors, writers, composers, and some academics who carry out much of their creative work beyond the walls of organizations and without the resources, supervision and structured work time that organizations usually provide.

Co-working Spaces Physical settings which offer a combination of individual and communal workspaces to autonomously creative people.

Creative Agents or Creators People who produce new pieces of art, literature, science, and technology.

Creative Cities Cities such as Paris, Milan, Tokyo, Vienna, New York City, San Francisco and Los Angeles which have been or are currently the site of noteworthy creative activity in particular fields.

Creative Environments Physical, social, and cultural environments which support and enhance the creative work of those who work and live within them.

Creative Seeds The initial “seeds” around which creative interests and activities sometimes develop. They often consist of newly encountered ideas, perspectives, images, sounds, objects, materials, processes, tools, or dream fragments which elicit the curiosity and attention of creatively-inclined people and which evoke creative activity.

Creatively-Active or Creatively-Engaged People People who are engaged in a creative project.

Creatively-Inclined People People who enjoys certain types of creative activity and who have a history of voluntarily, and often enthusiastically, engaging in those activities.

Designated and Protected Workspace A type of workspace that is “designated” in the sense that it is to be used primarily or exclusively as a person’s central place of creative work and is “protected” in the sense that it is not to be intruded upon, re-arranged, or “cleaned up” without permission. Such spaces may take many forms, including those of tables, desks, offices, studios, lofts, garages, basements, re-purposed factories, or capacious old barns.

Process- and Project-Entailed Challenges The psychological, material, and social challenges which creative processes and creative projects present to creatively-active people and the environments in which they work.

Introduction

Creative Environments

Creative environments help people function more creatively than they would in less creative environments. Because other entries in this Encyclopedia describe environmental factors which influence the creative functioning of people working within organizations and groups, this article will focus on environmental factors which often facilitate the efforts of autonomously creative people such as

writers, visual artists, designers, and garage or basement inventors, who carry out much of their relatively solitary creative work without the support, supervision, or resources which organizations typically provide. Reflecting the availability of relevant scholarship and data, this article will focus on environmental qualities and features particularly relevant to writers and visual artists.

Working Assumptions

This article is organized around the assumption that creative activities and projects present a variety of challenges to people who attempt to carry them out and to the environments in which they attempt to do so. It is also assumed and implicitly predicted that environments which help people meet such challenges will tend to support higher levels of creativity than environments which do not. For example, because some (but not all) people require periods of uninterrupted focus while engaged in certain phases of their creative activities, environments which make it easier to maintain sustained focus during those phases would be expected to support higher levels of creativity than environments which do not.

As this hypothetical example suggests, however, creative agents are not uniformly sensitive to or affected by any given project-entailed challenge such as the need for sustained periods of uninterrupted focus. For example, some creators may not require such periods and may not require any special conditions to experience them. Therefore, although it may be possible to identify environmental features that are important for many autonomously creative people, it will not be possible to describe or characterize an environment that is apt to foster and support the work of all autonomously creative people, even those engaged in the same type of creative activity. In addition, the fact that different types of creative activities (e.g., writing a novel, painting a still life scene, producing a piece of pottery) undoubtedly present creative people and their environments with different sets of challenges, makes clear the impossibility of being able to describe the characteristics of a universally creative environment. Furthermore, in the absence of quantitative surveys or studies of presumably creative environments, most statements in this article regarding the importance or prevalence of certain environmental factors will be qualified by terms such as “some” or “many” but almost never as “most” or “always”.

Creative Episodes: Common Elements, Features, and Associated Challenges

This section was constructed by (1) compiling a list of widely-cited and presumably relatively common features of creative activities, (2) drawing inferences about the challenges those features present to people engaged in them and to the environments in which they work, and (3) drawing inferences about the functional characteristics of environments that would tend to help autonomous creators meet those challenges.

Motivation. People are motivated to initiate and carry out creative activities by a variety of anticipated and experienced pleasures and satisfactions. Some of these pleasures and satisfactions flow directly from the activities themselves, and others are contingent upon anticipated and actual reactions of the outside world to the created products. The first category would include, for example, the pleasures people often derive from using their own imaginations, from physically manipulating their projects’ materials, or from creating some new in the world. The second category would involve matters such as the recognition and praise the creative agents receive from their peers, as well as evidence that their work products have informed, given pleasure to, or in some way benefitted those who come in contact with them. Most professionally creative adults who are financially responsible for themselves and others are also motivated by the hope that their creative work will enhance their financial well-being.

The nature of these motivations poses three challenges to the environments in which autonomous creators work. (1) Creative environments should contain or make possible the creation of workplaces in which process pleasures can be fully experienced. (2) They should contain relevant “audiences” who are able to derive or create value from the agent’s products and are capable of rewarding those who produce them with praise, recognition, monetary support, and opportunities for future work. (3) They should also contain people, social systems, and infrastructure (e.g. agents, editors, publishers, bookstores, and galleries) that help bring new products to the attention of such audiences. Environments which serve these functions well should support higher levels of creative activity than environments that do not.

Creative Seeds. Creative activity is sometimes triggered when creatively-inclined people come in contact with creative seeds. Seeds sometimes take the form of invitations, competitions, or commissions relevant to a creatively-inclined person’s creative interests. In other cases, creators decide to undertake projects which are available in the social or artistic-intellectual milieu as tasks and which are considered to be interesting and important tasks. Examples include writing the “Great American Novel,” writing an essay explaining in convincing detail how consciousness arises from activities of the brain, or producing a piece of art that captures the essence of the times.

More commonly, however, independent creators construct their own projects from what may be thought of as creative “seeds” which re-ignite and are assimilated to their ongoing creative interests. Seeds may come in the form of new ideas, images, sounds, objects, materials, processes, tools, and ways of thinking which are encountered in the outside world. The impact of Picasso’s contact with African art and masks nicely illustrates this phenomenon.

As a more prosaic example, a snippet of conversation overheard on a busy sidewalk or in a check-out line might become the seed for a new song, detective novel, piece of art, or nothing at all, depending upon whether it was overheard by a singer-songwriter, a writer of detective novels, a visual artist, or by someone who is not at all creatively-inclined. Creatively-inclined people also sometimes experience seeds emerging in the form of dream fragments or compelling feelings, ideas, or feelings which suddenly manifest themselves in consciousness. In other instances, creative seeds emerge from explorations and playful manipulations of the materials with which people are working.

The importance of seeds presents creatively inclined people with three challenges: (1) to place themselves in informationally and sensorially rich situations where they are apt to encounter new seeds; (2) to place themselves in or create settings in which internal seeds are apt to arise; (3) to place themselves in or create settings in which they are able to engage in the goal-free explorations and playful manipulations of the materials from which seeds often arise.

The corresponding challenges for environments are (1) to contain a rich panoply of seeds and (2) to contain settings or situations conducive to the emergence of “internal” seeds, and (3) to provide settings in which goal-free explorations and playful manipulations of their materials are possible and permitted.

Spaces and Places. The creative activities being considered in this article must take place in 3-dimensional spaces. In some cases these spaces may involve little more than a place to sit and write, although in other cases these spaces may involve larger and more complex spaces in which special materials and equipment can be stored and used. The challenge to creative environments is to contain such spaces and to make them available or to make it possible for people to construct them. The challenge to autonomous creators is to locate or construct them.

Some people and some creative activities (e.g., plein-air artists, certain writers) require or prefer outdoor spaces in which to work. Such spaces are often relatively quiet and solitary, frequently contain visually interesting vistas, are often located in appealing natural settings, and typically permit sustained and un-interrupted absorption in the task at hand.

Time. Creators typically would like to spend as much time as necessary on their projects and often wish to exercise considerable control over how their work time is configured. For example, some creators can or must work effectively in many short blocks of time whereas others need long periods of time. Some creators also have very strong preferences regarding the time of day, week, or even year and, in which to work. Some creatively-engaged people want to be able to plunge quickly into their creative work in response to suddenly emerging ideas or to a strong sense that they are really ready to work.

The challenge to these people is to find or “make” such time for their work and to find ways to control the configurations and availability of that time.

The corresponding challenge to creative environments is to help people find or make adequate work time and give them the freedom to configure and access that time as needed.

Reliance Upon Easily-Disrupted Concentration

I find it is very important to work intensively for long hours when I am beginning to see solutions to a problem. At such times atavistic competencies seem to come welling up. You are handling so many variables at a barely conscious level that you can't afford to be interrupted. If you are, it may take a year to cover the same ground you could cover otherwise in sixty hours.

Edwin Land, inventor of the Polaroid camera, quoted in *Bello (1959)*, p. 158.

As illustrated by Edwin Land's comment above, and as echoed by many others, some creators need protracted and uninterrupted periods of time during which they can become totally absorbed in their work without fear of being disrupted.

The challenge to people who have such needs is to create or locate time and space in which such uninterrupted absorption and concentration is possible. The corresponding challenge to creative environments is to provide the space and time necessary for such periods of uninterrupted concentration.

Reliance Upon Experimentation, Exploration, and Partially-Guided Trial and Error

People in many fields often find themselves relying upon experimentation and partially-guided trial-and-error during certain phases of their creative activities. Although some creators enjoy these processes, others are made anxious or embarrassed by their uncertain effectiveness. As a result, some creatively-engaged people are very resistant to having people looking over their shoulders as they work.

The challenge for creative people is to understand and manage such feelings and fears sufficiently that they do not disrupt their work. The corresponding challenge for creative environments is to help creators understand and manage such feelings and help protect them from unwanted observation.

Reliance upon non-conscious cognitive processes. Creators sometimes experience their work as being dependent upon the functioning of cognitive processes which are largely beyond their conscious awareness or control and which may or may not produce useful ideas. In some instances the products of these non-conscious processes appear unexpectedly in consciousness while people are engaged in relatively mindless and often relaxing everyday actions such as taking showers, napping, or falling asleep. Creatively active people have sometimes found leisurely strolls, especially those taken after lengthy or intense periods of creative work, useful in this regard. In other cases, people have attempted to consciously access these rather elusive processes by establishing what they consider to be particularly helpful external conditions which are often characterized by lack of distractions and a sense of peace and quiet. Reliance upon these marginally-controllable and unpredictably effective processes can also stir feelings of anxiety and self-doubt similar to those elicited by reliance upon experimentation and guided trial and error.

The challenge to creative people is to arrange external and internal conditions which facilitate conscious contact with the products of these non-conscious processes and to understand and manage the anxieties sometimes associated with reliance upon them. The corresponding challenge to those who manage creative environments is to help make such times and places available and to help people understand and manage the feelings of anxiety and self-doubt sometimes associated with dependence upon these processes.

Physical materials and tools. Many forms of creative activity require the use of certain physical materials, tools, and instruments such as specialized paints and brushes, appropriate clay and glazes, potters wheels, and kilns. The challenge to creative environments is to contain and provide access to such materials and tools and the challenge to creative people is to gain access to them.

Assistants. Creative activities initially undertaken as one-person projects sometimes require more knowledge and specialized skills than one person can provide. The resulting challenge to the creative agents is to accept their need for assistants and to locate and recruit them. The corresponding challenge to creative environments is to help people identify and accept their need for assistance, to contain and provide easy access to relevant assistants.

Solitary activity. Many autonomous creators work in settings in which they have little or no contact with other people for several hours at a time. Although this solitariness suits some people very well, and may in fact be one reason they have gravitated to these activities, the solitariness may be problematic for more extraverted people. The challenge to creative environments is to provide opportunities for solitary creators to engage in social interactions as desired.

Tentative completion. Creative projects must eventually be brought to initial completions despite the imperfections and undeveloped possibilities that are often disturbingly evident to those who created them. The challenge to creative people is to complete their projects despite uncertainties as to whether they are good enough to submit to the wider world. The corresponding challenge to creative environments is to contain peers or experts who can help creators make good decisions about when to consider a project finished.

Projection into and reception by the outside world. If creative products are to provide those who create them with the socially-contingent benefits they need and desire and if the products are to benefit people for whom they were created (their intended audiences) they must be projected into the outside world and made visible to audiences that are capable of recognizing, rewarding, and responding to them in motivationally satisfying and practically valuable ways. The challenge to autonomous creators is to find ways by which their finished projects can be brought to the attention of such audiences. The challenge to extended creative environments is to: (1) contain audiences which are able to derive or create value from those new products and are able and willing to direct psychological, social, and monetary resources back to the original creative agents and to those who helped bring the products to the attention of the relevant audiences, and (2) contain intermediaries (e.g., agents, publishers, gallery owners) and social systems that help bring new products to the attention of such audiences, and (3) contain social mechanisms by which appreciative audience members are able to directly or indirectly reward those who created the valued products and to those who brought the products to their attention.

The challenge to creators is to be flexible and extremely persistent in trying to push their work into the world. It is worth noting that J. K. Rowling's efforts to solicit interest in her initial *Harry Potter* drafts were rejected by 12 publishers before finding one that was receptive. Books and online columns directed to artists, especially young artists, consistently recommend persistence in the face of rejections by juried shows, galleries, and other gatekeepers that are preventing their work from being seen.

Characteristics of Sought-Out and Constructed Environments

The actions taken by autonomously creative people to seek out and construct creative environments for themselves constitute another interesting source of information regarding the nature of creative environments. Descriptions of those actions and the nature of the sought-out and constructed environment have been reported by autonomously creative people themselves as well as by journalists, biographers, sociologists, and historians. The following topics are frequently mentioned in these descriptions:

1. Designated and protected workspaces.
2. Socially permeable and familiar workspaces.
3. Writers and artists groups, clubs, collectives and cooperatives.
4. Artists and writers colonies and retreats
5. Creative cities and neighborhoods.
6. Supportive spouses, partners, and friends.

Designated and protected workspaces. Many autonomously creative people involved in relatively solitary activity construct or seek out primary places of work which may be described as "designated and protected" workspaces. These spaces take many forms, including that of tables, desks, offices, backyard studios, garages, basements, lofts, work-live spaces, barns, re-purposed warehouses, and secluded cabins. These spaces are "designated" in the sense that they are intended to be used primarily or exclusively as the person's central place of creative work. They are "protected" in the sense that those who use them often make clear to other people that the spaces are not to be intruded upon, re-arranged, or "cleaned up" without permission. The "protected" quality of these spaces certainly calls to mind Virginia Woolf's famous suggestion to aspiring young women writers that they should manage to obtain rooms of their own "with a lock on the door" (Woolf, 1929).

Some creators also try to make these work-spaces quickly accessible by establishing them within or very near the structures in which they live, though others find it easier to maintain the designated and protected quality of these workspaces if they work elsewhere. Ideally these spaces can be equipped and arranged to suit the user's work style and preferences for such matters as décor, lighting, and the presence or absence of background music. Such workspaces serve many functions in the process of supporting their users' creative activities.

Help sustain uninterrupted work. For many creators, the most valuable aspect of such spaces is the fact that they provide the physical and psychological space needed to engage in the uninterrupted and undistracted periods of absorbed, concentrated, and sometimes meditative thought which are so often crucial to their creative work.

Encourage and support self-imposed work schedules. The existence of designated and easily accessible workspaces also appears to encourage some creators to begin their work on self-imposed schedules, a function which organizations often provide people working within them but which autonomous creative agents must provide themselves.

Preserve work-in-progress. By permitting people to leave work-in-progress (e.g., unfinished canvases, pages ending in mid-sentence, partially completed gadgets, etc.) safely undisturbed between periods of work, these work-spaces reduce set-up time, but more importantly, help people quickly re-enter their previous frames of mind and easily pick up threads of thought which were laid to rest at the end of their last period of work.

Safe space for small "failures". Such settings also function as psychologically "safe" spaces in which it is possible to engage in the frequently unsuccessful experiments, explorations, and partially-guided trials-and-errors so often characteristic of creative work without fear of having others witness these many small "failures".

Motivational support. Such workspaces sometimes provide modest motivational support and encouragement in at least three ways. Because they can be arranged to meet the creative worker's individual tastes, they can enhance the pleasure experienced while working within them. In addition, if such spaces are used almost exclusively for creative work, the simple act of entering them may sometimes trigger the kind of focused creative work that has come to be associated with that space. Furthermore, if these spaces have been the site of previously successful work, they may reduce project-related anxieties by eliciting memories of those earlier successes.

Accessible materials and tools. Such work-spaces facilitate creative work by making the necessary materials and tools and often specialized information easily accessible.

Exceptions; It should be noted, that some very fortunate and flexible writers have reported that they can work anywhere they can physically write and therefore need no special places in which to do their work.

Socially permeable and familiar workspaces. Designated and protected work settings do not meet the needs of people whose circumstances prevent their using them such as parents who must work within sight and sound of people who they caretaker. J. K. Rowling, for instance, famously wrote parts of her first Harry Potter novels sitting in a neighborhood cafe with her infant resting in a nearby stroller, and a coffee machine moments away.

Familiar coffee shops, cafes, restaurants, and local libraries. Designated and protected workspaces also don't meet the social needs of people who find them too isolating. As a result autonomously creative writers who need to work in more social settings often turn to familiar and accommodating coffee shops, cafes, restaurants, and local libraries as places to work near other people. For decades, autonomously creative people in Europe and the United States have used cafés, bars, and restaurants as places to work as well as places to meet and mingle with one another, typically at the end of their frequently solitary workdays. The café life of Vienna and Paris, for example, has often been cited as an important factor in sustaining the creative ferment of these two cities. Historians and sociologists of art and literature have also cited the roles played by particular bars in the emergence and development of bebop jazz in Harlem in the 1940s, the New York School of artists and poets in the 1940s and 1950s, and the development of the beat poets in San Francisco's North Beach in the 1950s. In such settings creative people are able to satisfy some of their needs for social contact. Here, too, they are able to participate in conversations and creative interactions with other creatively-active and intellectually-lively people who expose them to new and, perhaps, the very newest, ideas, perspectives and methods in their field of work. Valuable information about possible venues and outlets for their work and about intermediaries who might help project their work into the larger world is also sometimes exchanged and in these conversations. Within such gathering places, autonomously creative people also sometimes experience implicit affirmations regarding the importance and ultimate value of the kind of work in which they are engaged as well as more personally-directed expressions of encouragement and advice.

Co-working spaces and writers rooms. Recent years have seen the emergence of increasing numbers of co-working spaces which serve some of the physical and social needs of autonomously creative people. These co-working spaces, (or "writers rooms" in the case of those exclusively serving writers) typically offer private and semi-protected workspaces as well as communal spaces that can be used to socialize and exchange information relevant to their work. Some co-working spaces include communal spaces that have been specifically designed or configured to facilitate potentially synergistic exchanges of information and possible collaborations between creatively-active people working in different fields.

Informal groups and clubs. Autonomously creative people also seek creative support and stimulation by creating or joining local writing or artists groups in which they can share work-in-progress, explore thoughts regarding possible future projects, and receive constructive critiques in supportive environments.

Collectives and cooperatives. Autonomously creative artists sometimes attempt to facilitate their own work by affiliating with artists' collectives and co-operatives. In such settings artists are able to share space, materials, equipment, ideas, perspectives, and experience what they often describe as "good energy".

Artists and writers colonies. Every year, thousands of autonomous artists and writers apply to attend one of the hundreds of artists and writers colonies located in the United States. The qualities of some of the most prestigious of these colonies such as Yaddo in New York and MacDowell in New Hampshire, reveal much about the kind of working environments which many, though not all, independent writers and artists desire. In both of these colonies artists enjoy 24-h access to designated and protected work-spaces in the form of appropriately-equipped studios. Lunches are typically delivered to the individual cabins or studios in ways designed not to interrupt work. Relieved of almost all

non-work-related responsibilities and distractions and provided with designated, protected, and well-equipped workspaces, residents are able to focus essentially all of their energy and attention upon their creative work. Communal dinners and gatherings in the evenings provide opportunities for residents to socialize, exchange ideas, and share work in progress. Though such colonies do not fit the needs of all autonomously creative people, due in large part to the separation from family they require, and though access to such colonies is sharply limited, the appeal they hold for many autonomously creative people is instructive.

Creatively-active cities and neighborhoods. In seeking creative environments in which to live and work, autonomously creative artists and writers are sometimes drawn to cities and neighborhoods that are heavily and often unusually densely populated with people involved in creative activities similar to their own. As mentioned earlier, Paris, New York, San Francisco, and Los Angeles are famous examples of such cities, although they are certainly not alone in this respect. The following reasons explain why certain cities function as magnets for creatively ambitious people as well as serving as incubators and sustainers of their creative work.

Populous, culturally diverse, and historically and contemporaneously supportive of the arts. Such cities typically contain:

- large numbers of other creators with whom ideas and enthusiasms can be shared,
- affordable spaces in which to live and work
- rich supplies of necessary and sometimes specialized materials
- potential assistants who have specialized skills
- patrons, benefactors, and sponsors who are interested in supporting autonomous creators.
- diverse and sophisticated audiences eager for new creative products.
- sophisticated intermediaries such as critics, talent scouts, and agents who are interested in identifying producers of new and creative work and connecting them and their work with relevant audiences
- numerous outlets and venues such as galleries, bookstores, exhibition halls, and public readings by which new creative work can be displayed to relevant audiences and potential patrons;

Informationally-and-sensorially rich cross-roads. These unusually creative cities also tend to be cross-roads through which people from many countries, cultures, and traditions frequently pass and destinations and to which they sometimes come to live and work. In so doing such people bring steady streams of creativity-relevant information and creative seeds in the form of new ideas, values, knowledge, images, colors, sounds, tastes, tools, and ways of thinking and doing things.

Attractors of creatively talented and ambitious people. Because of their creativogenic qualities, these cities tend to continue attracting creatively-talented and ambitious people from across continents and oceans, thus swelling the numbers of creatively-inclined people living and working in relatively close proximity to one another. Such increased numbers and densities tend to increase the likelihood that creative neighborhoods emerge, that planned and unplanned interactions among creatively-active people occur, and that ideas, enthusiasms, materials, work-spaces, and gathering places might be shared. As a result of these processes, of course, such cities tend to foster ever higher levels of creativity and become even more attractive to creatively ambitious people who might gravitate toward them. At certain points, however, such cities may become so saturated with people engaging in certain types of creativity that their capacity to support and attract new creators in certain fields wanes.

Creative cities not for all and not necessary. Autonomously creative people certainly do not need to live and work in creative cities to do their creative work. In the first place, many people simply do not like cities as places to live or are prohibited by practical considerations from doing so. In addition, many creative people do not wish to lose their sense of place, comfort, and belonging by moving to a city. Others do not want to be distracted from their work by the many seductive possibilities that cities offer, to become overly influenced by the highly visible and much-talked-about creative work of other people, or to experience themselves as little fish in big ponds.

Autonomously creative people have also begun reporting that new modes of communication and new ways of displaying and advertising their work made possible by the latest technologies are diminishing some of the creative advantages previously afforded by physical proximity to creative colleagues, potential patrons, audiences, and intermediaries. Many autonomously creative people are able to find and establish good working environments and creatively supportive local environments in smaller cities and towns. For example, writers groups and artists co-operatives can be established almost anywhere that a few similarly-intentioned writers and artists reside.

It should also be noted that many creative people who are attracted by some of the benefits of unusually creative cities but deterred by others, resolve their dilemmas by locating themselves outside of but within easy reach of such cities.

Supportive spouses, partners, and friends. In any location, supportive spouses, partners, and friends often play important roles in the lives and work of autonomously creative people. For example, autonomously creative people often acknowledge the important role played by people with whom they live in helping to establish and protect their workplaces. Spouses and partners are also often thanked for tolerating work patterns that sometimes deviate substantially from the social norm, by occasionally freeing up work time by relieving the creatively active person of some household obligations, and by tolerating problematic behaviors and mental states sometimes associated with intense involvement in creative activity. Spouses, partners and friends are also frequently identified as influential sources of personal encouragement and as people who affirm the fundamental value and importance of the kind of creative work being done. In some cases spouses and partners also serve as sounding-boards, first audiences, helpful critics, and friendly editors.

Caveats

Variability among good creative environments. Creatively-inclined people differ from one another in many respects. As a consequence, the environments and settings within which they will flourish creatively undoubtedly differ in ways that reflect those individual differences. As noted earlier in this chapter, for example, the conditions preferred by easily and not easily distractible people or by relatively extraverted and relatively introverted people may differ in substantial ways. Furthermore, the conditions, settings, and environments supportive of one type of creative activity, such as writing a novel, may not be most supportive of other types of creativity, such as producing a series of thematically related canvases or pieces of pottery. As a consequence, the environmental conditions most helpful to any particular creator working on any particular project may not be the most helpful to other people working on other projects. This suggests that the ideal macro-environment for creative people is probably one within which autonomously creative people have the freedom to migrate to or construct whatever particular environments best suit their individual- and project-specific needs.

Many of the varied environments constructed or sought out by autonomous creators would exhibit at least some of the environmental features and functions described here. The degree to which this proposition is true for autonomous writer and artists, of course, remains to be seen, as does the degree to which the analyses presented here generalize to other types of creative activity.

Creative Environments Helpful but Not Necessary

It is extremely important to recognize and emphasize the fact that very good environments are neither necessary nor sufficient for creativity to occur. As history shows, acts of creativity can and do emerge from very difficult or even hostile conditions, and as history also shows, creative efforts undertaken in highly supportive environments often fail. Although supportive environments are neither necessary nor sufficient for creativity to occur, it seems reasonable to suppose that they tend to increase the likelihood that creative activities will be undertaken and completed successfully within them. Establishing and seeking out creatively supportive environments may therefore be analogous to eating well, exercising, and not smoking. While such practices do not guarantee good health or long lives, they generally improve the odds. Given the inherent complexity and unpredictability involved in creativity, that seems all that could be hoped for.

The term destruction describes damage beyond recovery or repair, changing something into a state of non-existence. Through creation, on the other hand, something emerges that did not exist before. This fundamental distinction is, at least, the understanding one can get from consulting dictionaries and common language texts. The term ‘Creativity’ with its different notions and definitions is not discussed here (See Definitions of Creativity). However, it is important to note that creativity entails more than creation, for example it also has to provide value. Authors like Novitz (1999, p. 78) and others have argued that those who are ingeniously destructive cannot be described as creative. Furthermore, the technical term ‘Creative Destruction’ is closely related and discussed in more detail in a separate entry in this volume. Here, the focus is on the relationship between creativity and ‘destruction’.

Etymologically, destruction derives from the Latin ‘struo’ prefixed with ‘de’. ‘Struo’ has meanings similar to building, preparing, and arranging but the prefix ‘de’ reverses that meaning. The root also appears in words with other prefixes; in this context, most notably with ‘co’, which then takes the meaning of collecting, fabricating, and constructing. Therefore, the dichotomy of the “Creativity and Destruction” is already reflected in their linguistic root. For example, in the building industry, construction and destruction are used to describe opposing processes; one putting a new building in place, the other eliminating an existing structure. However, what is the meaning of destruction beyond its use in everyday language?

Destruction

The use of ‘destruction’ in the philosophical literature appears in Heidegger’s use of ‘Destruktion’ as destroying ontological concepts (see a discussion of the term in Botha, 2008). In his writing, he argues that ‘destruktion’ is necessary to overcome a tradition that is only self-evident and whose source is inaccessible to us. He posits that this ‘destruktion’ has a positive intent by deleting the ontological concepts of the past and therefore giving way to a better and contemporary understanding. Interestingly, the use of the term itself appears to be influenced by Martin Luther’s work. For example, Crowe (2006) argued that Heidegger’s introduction of the concept references the Latin source of the word in a similar way that Luther did and how it was sketched above. Moreover, Heidegger seems to reference Luther directly in his texts, which suggests that, even if it had not directly influenced the use of the term, Heidegger at least knew about it.

In an attempt to translate Heidegger’s concept of ‘destruktion’ to French and apply it to understanding linguistic concepts, Derrida introduced the term ‘deconstruction’. Based on the fundamental understanding that words only have meaning through their difference to each other, the term suggests that after taking apart its pieces, there is still something left.

Deconstruction influences theories in a broad range of disciplines beyond the scope of linguistics, such as in architecture, anthropology, and humanities and shares this interdisciplinary relevance with creativity. However, according to the reading of Gasché (1987), Derrida’s deconstruction is a “well-ordered procedure, a step-by-step type of argumentation” (page 3) which sets it apart from the sudden and often unexpected nature of creativity. In its step-wise progression, deconstruction more likely compares to well-structured analytical thinking, than to free-flowing creative outbursts. Therefore, Heidegger’s destruction, aiming at annihilating the underlying ontological concept, might be a better candidate to consider as an antonym for creativity.

Another seemingly related term is the notion of destructiveness was used by Fromm (1973). He observed that people either embrace or escape freedom and further identified three mechanisms for escaping freedom. Destructiveness, as one of them, refers to the withdrawal from the world by eliminating it. Instead of exploring or enacting freedom in the world, this destructiveness causes people to destruct everything else. While destruction and creativity share common factors such as their role across interdisciplinary settings, they appear to be principally dissimilar in their mechanisms of operation and their outcomes.

Creativity and Destruction in Literature and Art

In his magnum opus “Faust”, Goethe let Mephistopheles (the Devil) introduces himself with the words:

A portion of that power, Which wills the bad and works the good at every hour.

When asked what that is supposed to mean, Mephistopheles explains:

And so, then, all that you call sinning, Destruction,— all you pronounce ill-meant,—Is my original element.

and goes on explaining that this element has been a necessary and integral part in this world since its creation. Going beyond the simple dichotomy outlined above, Goethe contrasts creation and destruction as opposite ends of a scale, as well as naming them integral parts of the same force. Dr. Faust, the protagonist and a scholar whose search for truth brings him not only to the edges of science but also to social norms, makes a deal with the devil. They agree that Mephistopheles will reveal the desired knowledge to Faust until he is satisfied, and the Devil will earn Faust’s soul in return. Throughout the first part of the play, they explore the immediate and contemporary environment of Faust while in the second part, they explore the macrocosm and time itself.

‘Faust’ has been translated in many languages and has had a great impact on artists and researchers since its publication. Mikhail Bakunin, a Russian political writer as well as anarchistic theorist and activist, was well acquainted with Goethe’s works. When he wrote about the power of negation as a revolutionary act in his 1842 essay “The reaction in Germany”, unmistakably there was a connection to Goethe’s Mephisto: “Let us therefore trust the eternal Spirit which destroys and annihilates only because it is the unfathomable and eternal source of all life. The passion for destruction is a creative passion, too!” It was later paraphrased to “The urge to destroy is also a creative urge” and attributed to Picasso, for example by Banksy, a street-artist commenting on his intentional destruction of “Balloon Girl”, through which it was transformed into “Love is in the bin”.

Examples from performing arts and music might be even more obvious. Stage productions in theaters around the globe have de(con)structed plays on several levels, from the aesthetics of classic stagings, to the prose and the method of acting. Choreographers have destroyed the social link of dance with its formalization in ballet and destructed this performance dance with improvisation and dance theater. Musicians have destructed their precursors works and music itself for a long time. Most notably, Johann Sebastian Bach destructed his own compositions in trying to understand the science behind music, and even recombined identified elements to new pieces. With sample-based musical styles consisting of excerpts from other recordings, Jimi Hendrix’ and Kurt Cobain’s destruction of musical instruments and styles that challenge any previous listening customs, the musical industry provides a broad range of examples for destruction. As such, the contrast between destruction and creativity so often portrayed in art and literature begins to reveal the complexity of the relationship between the constructs, as well as our interest in their tangled association.

Creativity and Destruction in Science

The trajectory of science is often depicted as a continuous progression from the early observations of natural phenomena to the discovery of the Higgs boson, and from belief-driven communities to managing complex social systems. At most, certain discoveries, such as Newton’s understanding of gravity, are considered sudden leaps forward. Yet, this is only part of the history of science. To follow, if you will, the fall of the Newtonian apple through history, Albert Einstein saw a problem of aligning the laws of the electromagnetic field with Newtonian mechanics. His work can not only be considered a creative leap forward, but at the same time, his paper on general relativity was a destruction of a previous theory. With his work, he catapulted the discipline, Physics, into the second revolution or ‘new Physics’. Interestingly, Einstein’s rejection of the possibility that measuring one particle could affect a second through “spooky actions at a distance” (as he noted in a letter to Max Born) had to be destructed as well, to understand entangled quantum states.

Looking at the history of science, Max Planck’s observed “A new scientific truth does not triumph by convincing its opponents [...] but rather because its opponents eventually die” (often paraphrased as “science advances one funeral at a time.”). This hyperbole shows some similarity with Heidegger’s ‘destruktion’. And indeed, generalized into the philosophy of science, Karl Popper defined science as testable. Specifically, he stated that every test of a theory is the attempt to falsify it. According to his framework, science must be falsifiable and every new prediction or theory needs to prohibit things to happen as well as provide a possibility to falsify it. As a more contemporary example, Stephen Hawking followed up by theorizing that a single disagreeing observation necessarily disproves a theory, and therefore advances science itself. Consequently, science in its definition and theorization, does not relate to creativity. Rather, destruction enables scientific progress and the scientific way of enhancing knowledge is through the falsification of testable hypotheses. To exaggerate, science would be indistinguishable from dogmatic belief-systems if it was not for destruction in the form of breaking mental sets and falsification.

Aspects of Destruction

From the discussion so far, it seems that destruction and creativity appear to be on opposite ends of the same scale yet additionally linked in other ways. Destruction and the closely related concept of deconstruction, are not creating anything novel and useful, rather they remove or “un-create” something. But as is clearly depicted in the wide range of articles in this Encyclopedia, creativity encompasses many different dimensions.

In the 1960s, Rhodes distinguished between different aspects of creativity that should be considered when doing research, or rather suggests that any research can be considered to be either about a creative person, creative product, creative process, or creative press (Rhodes word for environment that started with ‘p’). Later Simonton and Runco extended these categories to persuasion and potential. Building on these concepts, Glăveanu (2013) suggested another terminology that addresses the same underlying ideas but emphasized creativity as part of a social system. He talked about artefacts, affordances, audience, actors, and action. The advantages and problems of these terms are discussed elsewhere, but what would happen, if these same categories were applied to destruction instead of creativity?

In that sense, a destructive actor has a negative connotation and refers to active people with challenging personality traits. They can have negative consequences for other actors as well as any of the other four categories. Often this means, that they criticize others in the best case or attack them in the worst case. Depending on how this person is enacting this destruction, this can have a number of consequences. For one, critique usually leads to a better overall result, because the people critiqued will try to find a way to respond to the attempted destruction. Secondly, any attack will lead to a defense, and if the defended idea outlives the attack, then this stands a test of time. In some sense, and borrowing terminology from evolutionary studies, the destructive person provides a fitness function for the creating person. Furthermore, to be truly and impactfully destructive, this requires novel and useful ways of attacking others.

A destructive artefact is an item that can be used to destruct other things. One very effective and prominent example is the atomic bomb. Its development required many creative actors and creative affordances. Despite its cruelty and detrimental political and environmental impact, it is, without a doubt, a creative and a destructive artefact. The same could be said about many other inventions and technologies humans have developed over the years.

A destructive audience is an audience that destroys an artefact. One example could be the person consuming a dish of a master chef. Even though the artefact is destroyed afterward, this is the purpose of it in the first place. Another example is a piece of art that is destroyed through the interaction with the audience. A very slow destruction are visitors in a castle or visitor center, whose presence alone wears away the steps in the staircases, and whose humid exhaustions provide a challenge to the observed artefact. Yet another example is the piece of art by Banksy that destructed itself the moment it was sold at an auction. By the unintended and unwanted consumption as a commercial product, the piece of art destroyed itself. In this particular case, it attracted even more attention, and some argued, that the destruction itself increased the value of the artefact. Certainly, the self-destruction was a creative answer to a certain problem in the creative industry. Similarly, audience unintentionally destructed the career of their favorite music bands in some cases, when the audience became too big and the music groups disbanded as a response to this. For example, ‘The Jimi Hendrix Experience’ famously disbanded in 1969 as a result of commercial success and reduced artistic freedom. While Jimi Hendrix explored different directions with the ‘Band of Gypsies’ while also reforming with the ‘Experience’ several times, this success was arguably the beginning of a descent even quicker than their rise to fame.

A destructive affordance could be the intentional or unintentional harmful environment in which many people live. A great range of examples illustrate that these situations can lead to creative ways of coping with them. East German musical groups, that were not allowed to freely speak up and feared censorship, occupational ban, or even jail, developed a whole set of harmless and misleading metaphors that they used to communicate their opinions. Survivors of hurricanes and other life-threatening situations have used artefacts in a creative way to manage highly destructive situations.

The Creation and Destruction of Norms

Having briefly explored the idea of the “destructive actor”, the following section focuses on how individuals might destroy norms in order to create or to be deemed creative. Previous research has argued that in order to be creative, or more specifically, in order to engage in divergent thinking, individuals are often required to break rules. It does not seem too ambitious to say that in order to *think outside of the box*, an individual might have to break free from a set of rules which usually guide their thoughts and behaviors. Take the artist who begins to experiment with new styles and techniques in their work, later resulting in the creation of new genres. In fact, the emergence of Cubism in the 20th century might be traced back to Picasso’s and Braque’s early experimentation with fragmented and abstracted objects, which deviated from existing techniques that focused on perspective drawing. However, these examples of breaking rules are not restricted to the arts, as the following examples from business contexts demonstrate. Take the innovators who setup low-cost airlines like Ryanair and personal transport companies like Uber. They challenged the established ways that major transportation operators ran their businesses and changed the rules of the transportation game. Globally, businesses and institutions are seeking these kinds of individuals; people who will “take risks” in order to find or create innovative ways to solve problems and so the demand for rule-breakers is high.

Nevertheless, is it not inappropriate to search out, praise, and reward rule breakers? Without basic rules, there would be chaos. Many *social norms*, the unwritten and informal criteria that govern the behavior of a group, have developed for good reasons. Although closely linked, the term “norm” cannot be interchanged with “convention” here. Conventions come with empirical expectations about how they should be followed. For example, a conventional “cream tea” in Cornwall (England) would be served to you in the form of scones with jam, Cornish clotted cream, and a hot cup of tea. You would probably be surprised if you were served an unconventional cream tea that comprised bacon and eggs instead. Social norms are more prescriptive in that they involve normative expectations, as well as empirical ones. So, spreading jam and clotted cream onto the scone with hands, rather than a knife, would probably offend observing people. While violating this norm of etiquette does not damage the welfare of someone else specifically, the act damages the reputation of the person who appears to not care about this social norm.

One could argue that social norms keep group members in check and stop them from crossing perceived boundaries and therefore potentially bringing harm to the group. Community members share these norms and maintain them through sanctions. For example, it would be considered inappropriate to use swear-words in public in many cultures. If someone were to go into the street and start yelling obscene phrases, this act would most likely offend people. Most members of a group would avoid behavior like this because of the disposition to conform to this norm; they would feel guilty and ashamed if they swore in public. Society would actively sanction the inappropriate use of swear words by others, and individual members are motivated to ostracize those individuals who choose to use indecent language. The reverse is true as well: certain subcultures require the use of codes and languages that would be inappropriate in other contexts. Not complying with these expectations is a similar breach of social norms within that particular culture.

However, this is not to say that all social norms lead to good outcomes for society. Many negatively perceived social norms exist across communities and can be detrimental to the wellbeing of group members. Consider how gender norms (social norms that relate to gender specifically) can influence thoughts and behaviors. The *empathic boy* or the *risk-taking girl* might not fit with long-held gender norms and unfortunately, this can hinder personal and professional progression and can lead to the development of detrimental stereotyping. Along with the prejudicial effects that social norms can have, the relationship between social norms and creativity can be paradoxical. Even when social norms are beneficial in maintaining society’s foundations, the predictability and stability with which they regulate behaviors might make them detrimental to creativity. For example, when people collaborate to make a creative product, they often conform to ingroup norms. However, when working individually, they may deviate from the ingroup norm and create novel artefacts. In environments that become predictable and stable, that do not encourage originality or innovation, institutions operating in an innovation-driven society favor non-conformists, willing to bend or break the rules who can produce creative outputs.

Given that rule breakers can produce these creative outputs, isn’t it right that they be sought out, praised, and rewarded? Perhaps this complex question can be addressed using a cost-benefit analysis. Do the benefits of breaking a rule and not conforming to a norm, outweigh the costs of destroying certain boundaries? Consider an example from academic and research contexts. Academia, at least in the western countries, has developed into a multitude of disciplines in the past century. Each of the disciplines has adopted a specific set of methods and terminology to communicate about the subjects of interest effectively. Alongside this, each scientific community has their own set of *social norms*. In recent years, multiple disciplinary publications gained considerable attention and had some impact across scientific communities. Currently, funding bodies support multiple disciplinary grant applications and expect involved scientists to research across disciplinary boundaries and consequently *break the social norms*. In interdisciplinary research, the cost is represented in communication difficulties and the additional work of integrating methodology stemming from different disciplinary backgrounds. Most obviously, this results in additional time required.

The benefit, on the other hand, is the possibility to address more complex research questions from a different perspective. One example from the academic world, was an interdisciplinary doctoral training center ‘CogNovo’ at the University of Plymouth. Research about the iterative emergence of novel and useful ideas on perceptual, individual, and system-level (dubbed ‘Cognitive Innovation’) was addressed from a range of disciplines. The above-average time to completing the PhDs and high-impact publications illustrate the two outcomes of the cost-benefit analysis. Valve, a gaming company, could serve as another example in the industrial domain. At some point, they abolished teams and hierarchies and gave their employees ownership over their products along with the freedom to work with anyone and physically move their desk to any location. The intention was to cross professional boundaries that traditionally belong to different teams to allow people to work together. For example, designers could directly interact with coders, and someone from marketing would be able to work with a mathematician developing the game engine. Similar cost-benefits are very apparent in this case as well, as Valve had the highest per-employee profit in the industry at this time, but were also well-known for missing intended release dates.

In both illustrated cases, breaking the social norm of working only within a discipline or profession came at the manageable cost of requiring additional time, while yielding beneficial value. Nonetheless, what happens when breaking a different kind of boundary? Let’s consider an alternative case. Types of motorized transportation are not only considered to be one of the biggest global polluters of our time, but their exhaust fumes are also the cause of many deaths each year. Therefore, there is a societal expectation that the manufacturers of these vehicles, reduce the emission of these gases through effective production practices. For many, the moral obligation of reducing harm to the planet as a whole drives this societal expectation.

The way the ‘diesel-gate’ scandal is currently portrayed suggests that at some point, the technological progress of car manufacturing was not as fast as engineers, managers, or maybe even the general public expected it to be. At some point, an additional device was added to vehicle engines that did not reduce the release of nitrogen oxides (the outputs most relevant to air pollution), but instead, intentionally deceived everyone into assuming that the exhausts were less harmful than they were. The vehicles

with assumed low emission values were then heavily marketed by the manufacturer and became a considerable success. To achieve this, the people who knew about the additional device deceived their colleagues, families, and society by breaking a set of protocols. This initial change introduced in the small-engine fleet of one manufacturer increased the pressure on engineers working on other engines in the same company and their competitors. Quickly, a number of copy-cats used the same 'creative' workarounds when they could not technologically solve the problem. While in this example the whole planet loses, these individuals who knowingly broke the protocols or willingly accepted others doing it, destroyed normative boundaries and benefited financially.

These instances of rule breaking and destroying normative boundaries might result in experiencing an aversive reaction, and ethics can help unpack this tension. More specifically, by turning from considering social norms to *moral norms*, which are the rules that help individuals figure out how to behave *appropriately*. These rules have "universal content" and adherence to them is often independent of what others do (Bicchieri, 2014). For example, most people would agree that killing someone is morally wrong because it violates the moral value of a duty to care for others. Nevertheless, whether (and which) moral values are universal (or cross-cultural) is not discussed at length here. There does appear to be variation, even in moral values that would arguably be considered universal at first glance. For example, consider the number of honor killings in many subcultures; these are a reminder (perhaps to Western societies specifically), that a moral diversity exists in the modern world. Also in Western societies, certain professions are trained in killing people to protect the social norms of the society by violating the moral norms of the individual.

In the diesel-gate scandal, the actions of engineers and managers in deceiving and harming others, in order to further their success, appears to violate the moral values of trustworthiness and respect. The focus on moral costs raises the stakes, and it is harder to gauge whether the pay-off between destruction and creation is justified. This is not to say that the evaluation of these and similar situations will necessarily be negative. In a broader context, unethical behaviors that result in intriguing, exciting, and innovative outcomes are often admired as clever forms of trickery. In fiction, a large audience certainly seemed to admire Danny Ocean and his collaborators when they broke into a multi-million dollar vault using an innovative set of plans in the film *Ocean's Eleven*. Rule-breakers are often praised and acknowledged for their innovative practices. In fact, across several experiments, research has found that creative forms of unethical behavior are judged less severely than less creative forms of unethical behavior (Wiltermuth et al., 2017). This distinction demonstrates how complex the interplay is between moral norms and actual morals; individuals might value moral universals like obedience, but they also possess an affinity for those individuals who dare to be different. This complexity adds to the struggles that organizations face in providing both clear boundaries and freedom, to motivate creativity but not unethical behavior.

Deception: Destructive or Creative Communication

The boundary between creative versus destructive is somewhat tangled, particularly when appraising unethical behaviors. Research examining the destructive side of creativity has often focused on dishonesty and deception specifically (e.g., Gino and Ariely, 2012). Of course, deception can take many forms and the boundary between deception and lying is often unclear. Here, the term "lie" is an act to intentionally mislead others when they expect honest communication. This focus on deceptive communication is not surprising, given that lying is probably one of the most common wrong acts. While some have argued that dishonesty involves breaking a social principle that the truth should be told, others have explored morally-focused accounts of deception stating that lying is bad and immoral and nobody likes a liar. Here is a more detailed example of the implications of deceptive communication. Moral values like honesty and trustworthiness, are complex because they require taking into account people's motivations for lying and the outcomes of their deceptive behavior. It seems reasonable to assume that honesty is a moral good and that dishonesty is a fundamental moral wrong, but the relationship between honesty and moral action is not straightforward. Note the distinction between what might be considered *bad* (as the opposite of good) versus what might be considered *wrong*. Some argue that only actions can be *wrong*: while someone falling off a cliff would be bad, pushing a person off a cliff would be wrong.

However, in varying numbers of instances, it might be considered acceptable to lie. For instance, people might *tell a white lie* to a friend who bought them a present that he or she didn't like – "Yes, I just love it!" – in order to protect their feelings. In these instances, lies are motivated by compassion and individuals who tell these so-called "prosocial lies" are judged to be more trustworthy. In fact, in some cases, it seems a moral obligation to deceive. If you were approached by an assassin and asked where their *target* was, would you reveal their victim's location? In these cases, it seems that honesty is not a moral good in all instances and neither is dishonesty always morally wrong.

Aside from situations in which lying might be morally justified such as in the case of protecting someone's feelings or sparing someone's life, what about using deception to produce creative outcomes? For example, a competitive salesperson, who is willing to bend the rules and provide additional incentives and leniency to their customers, is likely to benefit financially and is therefore motivated to continue acting deceptively. While hopefully this kind of self-interested deception would be punished and discouraged by an individual's moral compass, this is not always the case. In fact, individuals can manage the balance between maintaining a positive self-image and a desire to maximize self-interest through "self-serving rationalizations" which enable them to justify small amounts of deception or dishonesty. As such, instances in which individuals can justify dishonest behavior will likely promote some form of dishonesty.

Research has shown that simply thinking that you are creative, can lead to a sense of entitlement, given that creativity is perceived as a valuable attribute. This sense of entitlement can then enable individuals to justify questionable behaviors using self-serving rationalizations. So in the case of the salesperson above, the extra income from their customers and praise for high customer

retention they receive as a result of their creativity, might lead the salesperson to justify further deception and dishonesty because they now "... feel licensed to cheat" (Gino and Ariely, 2012, p. 455).

Personality Traits, Creativity, and Destruction

Personality traits play a role in shaping the actions of the "destructive actor". Research indicates that individuals with creative personalities are more likely to engage in unethical behavior (such as cheating) and as we explored previously, this appears to stem from an ability to justify dishonest behaviors. Consequently, it seems as if dispositional creativity directly relates to destructive acts. However, are these traits also associated with creativity? "Destructive personality traits" is a relatively broad term that might include traits that promote self-destructive tendencies (which are discussed later in this section) but also traits that motivate destructive acts against others. Focusing on the latter, the next section will address socially-averse personality traits that comprise the Dark Triad (narcissism, psychopathy, and Machiavellianism) and their relationship to both destruction and creativity.

The Dark Triad and Creativity

Narcissists have an exaggerated sense of self-importance and a strong sense of entitlement. Like the other Dark Triad traits, a narcissist's destructive tendencies might appear in the form of the manipulation of others and callousness toward them. In the previous section, the point was made that merely thinking of oneself as creative can lead to a sense of entitlement. This increased sense of entitlement can result in more creative outputs. Given that narcissists have an inflated sense of entitlement, perhaps it is not surprising that individuals high on narcissism believe themselves to be more creative. This observation seems to support the theory that narcissists, being self-aggrandizers, exaggerate their accomplishments and overestimate their creative potential relative to others.

While research suggests that narcissists are no more proficient at coming up with creative ideas when their performance is objectively measured (Goncalo et al., 2010), others will often rate them as more creative because they display the prototypical traits of a creative individual. More specifically, individuals high on narcissism have high levels of self-confidence which enable them to sell their ideas more enthusiastically. This art of persuasion could explain why narcissism is a predictor of leadership emergence (Grijalva et al., 2015). How narcissism might contribute to creative efforts becomes even more complicated, when we consider the finding that narcissistic group members boost overall group creativity, even if they do not (objectively) perform more creatively in isolation. Again, the interplay between destruction and creation in these individuals appears to be tangled. Importantly though, despite the apparent destructive nature of narcissistic traits, it seems that collaborating with these individuals can, in fact, produce "... a valuable source of creative tension" (Goncalo et al., 2010, p. 1493).

Like narcissism, high psychopathy often relates to destructive tendencies such as lack of empathy and callousness toward others. As a triarchic construct, psychopathy couples with disinhibition, boldness, and meanness. As well as independently exploring the link between narcissism and creativity, research also investigated the relationship between psychopathy and creativity. For example, Eysenck (1995) explored the relationship between psychopathology and creative genius noting that "... actual psychosis is destructive" but that "... high psychopathology short of diagnosed psychosis is apparently beneficial" (p. 117).

In fact, the prosocial psychopath model of creativity suggests that a few highly creative personalities share some neurophysiological features in common with individuals with psychopathic traits and that traits related to psychopathy such as boldness, correlate with creative achievement. This link between psychopathy and creativity is thought to derive from emotional disinhibition. Again, the picture of the interplay between psychopathy and "prosocial" or creative acts, is far from simple. In fact, in broader investigations of the relationship between the Dark Triad (narcissism, psychopathy, and Machiavellianism) and creativity, research has found that both psychopathy and Machiavellianism are positively associated with harm-based creativity. For example, in a study utilizing divergent thinking tasks, answers for using a brick as a weapon received a higher score than constructive uses. Results suggested that individuals on the spectrum further toward these "darker shades" of the Triad also show forms of creative expression that are biased toward destruction.

The role of individual differences here, does not stop at creative and destructive dispositional traits. The process by which personalities are shaped across lifetimes might be understood as a sequence of creation and destruction. Self-creation unfolds from birth as we meet a number of developmental milestones and are motivated to reach new limits and achieve new goals. At the same time, individuals also engage in a number of self-destructive behaviors and processes. Like creativity, self-destruction might be discussed at the social, psychological, and physiological levels. For example, withdrawal from a peer group or the incapability to participate in social life, leads to the destruction of the self within its surrounding society. Different phenomena such as decreasing cognitive and perceptual abilities drive the individual's psychological destruction. Often these factors are intertwined with physiological decay and are considered to be finalized by the biological death of a person.

Malevolent Creativity and Benevolent Destruction

This entry explored the relationship between creativity and destruction at a conceptual level, demonstrating a binary dichotomy based on the definition but also explored, was the complex interplay between processes and people that both create and destroy. Normative considerations regarding the relationship between creativity and destruction focused on whether the benefits of

destroying something to produce a creative outcome, outweigh the costs. Taken together, it seems that evaluations of single creative and destructive acts or the dispositions of creative and destructors actors rely on the understanding that both creativity and destruction can be assigned either a positive or negative valence. For example, creativity will not always be benevolent; the “dark side” of creativity suggests that individuals will sometimes act dishonestly for self-interested motives and bold or callous individuals will often engage in harm-based creativity. On the opposite end of this scale, destruction will not always be malevolent; individuals who strive to destroy harmful social norms do so because those norms pose a threat to their group and innovative individuals will often break particular social rules in order to innovate and inspire. While most societies theoretically desire to both condemn destructive acts and reward creative acts, to punish rule-breakers and praise innovators, and to ostracize antisocial individuals and welcome individuals that inspire, a binary dichotomy of creation versus destruction does not apply to all actions. In some cases, the actor is both creative and destructive. Perhaps destruction requires the same detailed discussion as creativity, to further distinguish it in its personal, temporal, linguistic, and normative dimensions.

Introduction

Changes of perspective are related to creativity in many different domains. Many artistic styles develop, for instance, when an artist or group of artists recognizes the need to change the way the world is viewed. The new style, in this sense, presents an alternative perspective.

Dramatic shifts also characterize the sciences. In Thomas Kuhn's well-known model, *normal science* involves the accumulation of factual information, which is collected with theories and methods that reflect a similar perspective of the world. At some point, however, existing theories are found to be inadequate to explain certain observation. A dramatically new perspective results from a paradigm shift. These are dramatic in the sense that they do not merely extend the thinking that came before but instead introduce a completely new way to view the world. Examples include the scientific revolutions of Copernicus, Darwin, and Einstein.

Albert Einstein seemed to have developed some of his most significant insights using thought experiments. He imagined himself riding a beam of light, for example, or on a train moving in the opposite direction to another train. These thought experiments gave Einstein a unique and useful perspective on the relativity of our physical world.

Picasso has often been quoted as saying that he learned to paint only after he remembered how to think like a child. Picasso was well aware of the assumptions and routines adults too often develop. More often, an adult's perspective will differ from that of a child.

One of the most dramatic changes in literature occurred when Dorothy Richardson and James Joyce developed stream-of-consciousness styles. They shifted the perspective within the novel, away from the observer or third person and to the individual or protagonist.

As Runco described this in an article on problem finding,

Richardson, author of *Pilgrimage*, seems to have been the first to use stream-of-consciousness in literature. Her insight was that a new perspective in literature was needed. This led her to reorganize her thinking and writing about the protagonist of *Pilgrimage*, Miriam Henderson. Rather than describing the character and her actions, Richardson began to *take the character's point of view* and describe the 'inner psychic existence and functioning' for the reader.

Runco (1994: 374)

Doris Wallace is quoted on this issue of 'inner psychic existence and functioning.' Wallace concluded that the organization and reorganization in Richardson's writing reflects a type of problem finding, for no one before Richardson saw the need for a new perspective. Wallace also described the history of insights, arguing that they are constructed over a long period of time. This is apparent in the work of Darwin and Richardson and other creators who had insights only after they considered a problem for a long period of time (Wallace, 1991).

Perspective Shift is Fundamental to Creative Processes

As this discussion of paradigm shifts may suggest, shifts in perspective, like those of Copernicus, Einstein, and Darwin, can lead to dramatic changes in world views. In this sense the shift is the mechanism which leads to the insight. Shifts of perspective may underlie other processes related to creative work. Recall here that shifts in perspective may be literal or metaphorical. Consider

the tactic (often used in the research and in programs designed to enhance creative potential) to 'stand the problem on its head.' The idea here is to turn the issue upside down – to obtain a different view. Programs sometimes suggest magnifying or minifying a problem. In the former the problem or its representation is enlarged. In the latter the problem or its representation is reduced. Again, this requires a shift of perspective. Another recommendation for finding creative ideas is to stand back and change one's 'level of analysis.' Related to this is the suggestion to alter the medium being used to represent the problem. Use words instead of numbers or pictures instead of words. There may be several benefits to these changes, but certainly one of them is that a change of perspective is involved.

There are various explanations of the *incubation* that is often tied to creative insight. There may be a preconscious relaxation of constraints, allowing alternatives to be found. Incubation may be effective precisely because it allows one individual to find a new perspective and to break away from an existing viewpoint. Most of us have probably had the experience of taking time away from some difficult problem, only to return and solve the problem easily because we saw something more obvious after the break (the incubation) that we were overlooking or taking for granted before.

Perspective Shift and Cognitive Flexibility

The relationship between perspective shift and creativity is also shown in the importance of cognitive flexibility in generating creative ideas. Cognitive flexibility refers to the mental ability to shift from one idea or perspective to another in order to overcome the fixed association and generate new associates. It is mainly manifested in the use of broad cognitive categories or perspectives and frequent switches among cognitive categories. Empirical studies have supported that using perspective shifting or perspective taking increases the generation of creative ideas. This can be explained by a dual process theory of creative cognition, which suggests that both associative and executive processes are involved to produce creative ideas. Further, the ability to generate creative ideas, or the ideas that are original and appropriate, is a function of cognitive flexibility and cognitive persistence. Specifically, cognitive flexibility may lead to high level of originality whereas cognitive persistence may lead to high level of appropriateness.

Developmental Trends

Individuals may intentionally change their perspective in order to increase the likelihood of a creative insight. There may, however, be developmental trends in the capacity for shifting perspective. These would suggest that changes of perspective are more difficult for younger individuals and perhaps should not be encouraged early on. Most obvious here is the tendency for young children to be *egocentric* in the sense that they cannot take someone else's perspective. Only in adolescence do individuals recognize that others hold different perspectives from one's own. To the degree that these general cognitive tendencies relate directly to creative problem solving, we would expect age differences in the capacity for using changes of perspective in a tactical manner to increase one's originality and creativity. This certainly would be consistent with theories of metacognition, with younger children not recognizing that tactics and intentional efforts are necessary for problem solving.

Mood Swings and Perspective

A large amount of attention has been directed to the affective disorders of creative persons. Typically these are bipolar disorders, which are characterized by mood swings. Such mood swings may be functionally tied to creative work; and here again it is possible to speculate that there are relevant changes of perspective. Put briefly, the mood swing may provide the individual with more than one perspective of his or her own work.

This hypothesis is supported by anecdotal reports by creative persons that they are (a) highly productive but not critical when they are experiencing the mania of a mood swing, and later (b) highly critical – an effective editor so to speak – when they experience the depression which characterizes the opposite extreme and other polarity of the mood swings.

Mood states also influence perspectives through the effect of cognitive flexibility. In general, based on the dual process model, positive mood states influence creativity through the stimulation of cognitive flexibility and negative mood states influence creativity through the stimulation of cognitive persistence. However, the relationship is far more complex than it appears. For instance, the effects of positive mood states on creativity can only be found with the mood states such as happiness and elation, but not for others such as feeling calm and relaxed.

Cognitive and Extracognitive Influences on Shifts of Perspectives

Shifts of perspective require particular cognitive capacities. Some shifts may require visualization or other sensory capacities, as would be the case when the individual literally imagines what another perspective would look like. Higher order abilities are also required. The shift may, for example, take the individual to a hypothetical perspective; and this requires formal operational thinking. The shift may require that the individual imagine him- or herself in someone else's shoes. That is a special kind of

hypothetical reasoning that reflects *sociocentric thinking*. This too is cognitively demanding. Young children, for example, are egocentric rather than sociocentric and unable to shift to someone else's point of view. This is not a matter of choice but is instead a reflection of the maturity (or lack thereof) of the nervous and cognitive systems.

Extracognitive capacities are also required for shifts. Open-mindedness is required, for example, because the individual must acknowledge that there are other possibilities. A courageous attitude may be necessary so the individual is willing to try something new, and perhaps take a risk with it. Ego-strength will certainly be necessary. This provides the confidence to actually use one's personal creative license. Ego-strength may be especially important because creative ideas and insights are often unconventional; and if they are found by shifting perspective, that shift may be away from conventions, norms, traditions, and expectations. It is analogous to what has been called *artistic license* but it may not involve art; hence the term *creative license*.

Beauty is in the Eye of the Beholder: Perspective Differences Influence Judgments of Creativity

To the degree that creativity is a social phenomenon, it is dependent on interpersonal judgments – and these will very likely vary depending on the perspectives held by the different persons involved. As a matter of fact there is a principle in social psychology that predicts that two people will tend to form different hypotheses to explain their actions. The person doing the action will tend to explain it in terms of the immediate environment and context. An observer of the same action will focus his or her explanation on the person involved. This follows from the divergent perspectives of the two individuals. The person doing the action will tend to look away from him- or herself. Their physical perspective will be oriented outward. The observer, on the other hand, will probably see the person doing the action as salient and spend most of the time viewing that actor. This may apply to creative work, and a creator may explain his or her work contextually while an audience will emphasize the creator. The most important point is that discrepant perspectives lead to different opinions.

No wonder that (a) different judges often disagree about the qualities of creative work, or even about the level of creativity in the work, and (b) opinions of creators often differ from those of audiences and judges.

This line of reasoning about interpersonal judgments implies that implicit theories are relevant. Implicit theories are held by parents, teachers, or any group of nonresearchers. Scientists and researchers hold explicit theories, which are explicit in that they are articulated, shared, discussed, presented, published, tested, and so on. But nonresearchers also have stable views of creativity. They are not shared nor articulated, so they are implicit instead of explicit. They are quite important since they can lead to the expectations that in turn have a notable impact on development and behavior.

Simply put, implicit theories probably assume a particular perspective. Consider the example of a teacher whose perspective on creativity is that it is domain specific. He or she may not look for an artistically creative student to do much in science or some other domain. Conversely, if a teacher's perspective on creativity reflects the implicit theory that creative talent is general rather than domain specific, he or she might expect the artistically creative child to also perform in an original fashion in science and other domains. Much the same applies to the explicit theories of creativity held by researchers and individuals actually studying creativity. Their perspectives will lead them to expect certain things and ignore others (i.e., those traits that are thought to be irrelevant to creativity). The point is that there is probably a strong relationship between implicit theories and particular perspectives on creativity.

The effect of perspective taking on the judgment of creativity is also confounded by other factors. For instance, individuals who are more prosocially motivated tend to adopt others' perspectives. This in turn helps these individuals to integrate different perspectives and create more useful products as well as understand what product is useful for people working with them. Diversity in a team also increases creativity because a more diverse environment enhances team members' willingness to consider others' perspectives. In addition, the effect of perspective taking on the judgment of creativity also depends on how much information is provided for the judges about judged products and the individuals who make these products. For instance, a group of undergraduate student raters provide significantly higher ratings for the products when asked to take the perspectives of the individuals who make the products than when they are only told the age of the individuals who make the products.

Conclusions

Shifts of perspective are fundamental to several facets of the creative process. Some tactics may work effectively because they force the individual to shift perspective. Even though perspective is not mentioned in many programs which present recommendations to individuals who hope to maximize their creativity, a change of perspective may be implied in some of the recommendations that are suggested, and its occurrence (a shift of perspective) may explain the benefits. A change of perspective may have several benefits. A shift of perspective may, for example, break the individual's routine and allow him or her to find an approach that is uncommon or novel. Novelty is of course a correlate of originality; and originality is in turn vital for creative insights. Shifts of perspective may thus have their effect because they lead directly to novelty. The breaking of routine may be sufficient for the finding of creative ideas and solutions. Much research has demonstrated that fixity precludes originality, and that avoiding fixity or breaking one's mental set can lead to original problem solving. The benefits of changes in perspective are numerous.

Futures studies The study of the future, also known as futurology or foresight.

Improvisation The ability to create in the moment.

Regenerative culture A worldview that see humans as connected to and collaborating with nature and other human beings.

Social innovation A discipline that approaches social problems from the perspective of innovation.

Introduction

Human creativity shapes the future. Creativity is how the future comes into being, and human beings are only beginning to see how they are creating the future. The creativity of the modern age led to tremendous progress in science and technology, leading to rapid social change. The very forces that led to progress are now viewed as contributing to the great problems currently facing humanity, whether environmental, economic, or social. Creativity and innovation are drivers of the economy, and there is an increasing awareness of the importance of creativity. Creativity is central to futures visioning processes and to scenario planning. But there is also debate and questioning about *how* creativity is being used, what kind of futures are being created, to what ends, and by whom.

Overview

Thinking about the future poses any number of challenges. Perhaps the biggest challenge is how one can even begin to think and know anything about something that hasn't happened yet. Nevertheless, history tells us human beings have always wanted to know about the future and what it holds. Prediction has been a continuous thread through humanity's interest in the future, often for reasons of survival, whether to predict the effect of weather on agriculture or threats to life and limb from marauding visitors. Attempts at predicting the future have included the mystical (e.g. clairvoyant visionary seers), the cosmic (astrology), the relatively pedestrian (e.g. extrapolating from present trends), and more recently high-tech forecasting (e.g. Big Data).

Along with attempting to predict the future, human beings have *created* the future. They have envisioned futures utopian and dystopian, created new technologies that transform the way they live and work, and in their everyday choices and decisions willy-nilly created the direction of their lives. Individuals play a creative role in their future through their imagination, actions, and decisions.

Looking back on their lives, most people find that some of the most critical events and choices were unpredictable and indeed serendipitous. The future can be full of surprises which can range from finding the love of one's life to winning the lottery to earthquakes, hurricanes, and plagues of locusts, as well as a lot of less dramatic yet unexpected events and experiences. History has notable examples of the unexpected from the ripple effect of an assassination in Sarajevo in 1914 to the fall of the Berlin Wall to the election of Donald Trump. The world seems to be getting more unpredictable as it becomes more interconnected and interdependent through instantaneous communication and the networked society. People do not create the future in a vacuum, or exclusively in the unsullied province of the imagination. People create the future with the materials and realities at hand. They can respond to unforeseen creatively, or by trying to keep doing what they've always done.

Today there is increasing agreement among futurists and social critics that the world is currently in a period of significant transition, an in-between state that is marked by the frequent use of the prefix “post-” to describe it, such as post-industrial and post-modern. The British futurist Ziauddin Sardar stated that as a result of this transition society is now in postnormal times. In postnormal times, nothing seems “normal” anymore and chaos, complexity, and contradictions are its defining characteristics (Sardar, 2010). Society has left one age behind but has by no means settled into a new order, if indeed there will be one. Modernity has exhausted itself, in this view. Science, technology, industry, appeared to provide solutions for the challenges of existence and were seen as sources of a bright future. They were the drivers of progress. But the seemingly limitless faith in humanity’s capacity for betterment has increasingly turned to skepticism and even distrust, with an awareness that science and technology, and visions of progress cannot be insulated from human greed, errors, and illusions. Futurists and social commentators agree that as a result of this transition, this in-between state, the future is increasingly uncertain. Any number of terms have been used to capture the uncertainty. The Polish sociologist Zygmunt Bauman refers to current times as Liquid, fluid and ever-changing, leaving behind the Solid world of Modernity. The US Army War College uses the acronym VUCA, which stands for Volatile, Uncertain, Complex and Ambiguous to describe the current global situation.

Science and technology have been the biggest drivers of social change, particularly in the last 200 years. They are central to how humanity has created its futures. But the creativity of the arts has also played a role in society’s views of the future, science fiction being but one notable example. The impact of music, the visual arts, and literature has been significant. *Pamela, or Virtue Rewarded* by Samuel Richardson was published in 1740 to huge success. It was the first novel in the English language, and arguably sparked an explosion of the imagination and the age of Romanticism. Ideas, beliefs, and philosophies also shape the future. Political and economic ideologies like communism, capitalism, and socialism, human creations one and all, have transformed societies across the globe, for better or worse. Religious movements with their rituals, beliefs, and codes of conduct have shaped lives, in some cases with very definitive ideas about our futures in the afterlife. Human beings create theoretical frameworks to interpret the world, and these theoretical frameworks, in turn, shape human beings and their worlds.

Creativity and innovation have become central to the new economy and play an essential role in new disciplines like Social Innovation and Design. Sardar stated that what is most needed at this time are creativity and imagination, because as the old world is dying a new world can be envisioned and enacted. But it seems that creativity itself is changing. The creativity of Modernity, exemplified by the image of the lone genius decontextualized from the larger environment, may not be the creativity of the 21st century. A new contextual and relational understanding of creativity is emerging and increasingly influencing the way some groups are envisioning and creating alternative futures.

Brief History of the Future

What will the future bring? This question continues to be asked by human beings all over the world. History shows there have been many different ways of addressing it. Two ancient divination systems, the Chinese I-Ching and astrology, are still popular today. Both can be dated to approximately 3500 years ago. While they are dismissed as pseudoscience by the scientifically inclined, their continuing popularity indicates that our interest in divining the future has not abated. In recent years, US President Ronald Reagan was known to consult an astrologer who advised on such things as propitious times to meet with foreign leaders and sign agreements. In the early 21st century, clinical psychologists are increasingly finding clients who draw on the language of astrology.

The Industrial Revolution and the modern era led to a great acceleration in the rate of social change in Europe. Science and technology transformed manufacturing, agriculture, medicine, and transportation. The concept of progress emerged in Europe around 1680 and was fully developed in the 19th century. Before that time there was no sense of continuous improvement—if anything, the notion of a fall from a Golden Age was not unusual. The idea of progress stressed the value of reason and its application to science and research, the importance of technological and economic growth, and the achievements and superiority of European civilization.

The notion of progress was deterministic, holding that there is a linear inevitability about human betterment. This in contrast with earlier views that saw a Golden Age receding ever further in humanity’s past, or viewed time as circular rather than linear, with patterns of growth and decline. This linear view of the future inevitably led to predictions about what the future would hold, primarily focused on how new technology would change everyday lives. Advertisements were breathless with the promise of what science and technology would bring to every aspect of people’s lives. Popular images of the future dating from 1900 or the 1950s and 1960s show remarkable new technology, particularly of the flying kind, but virtually no changes in gender roles, for instance. In highly popular 60s television shows such as *Lost in Space* or *The Jetsons*, mom is still in the kitchen, albeit aided by new domestic marvels. It is perhaps not surprising that reviewing the vast and lively imaginary of predictions and science fiction scenarios of that time people of color barely appeared, and nature is often hard to find. Visions of the future say as much about current society as they do about the future. But beneath the optimism and faith in progress, Mary Shelley’s (1797–1851) *Frankenstein* already explored the dark underbelly of human ambition coupled with the powers of science.

H.G. Wells (1866–1946), a polymath and science fiction writer, is often seen as a founder of future studies. Wells wrote a book describing what life would be like in the year 2000, as well as such classics as *The Time Machine*, *The War of the Worlds*, and *The Island of Dr. Moreau*. Wells felt strongly that the disciplined study of the future was necessary. Along with the earlier work by Jules Verne (1828–1905), Wells established a strong connection between imaginative fiction, the study of the future, and the images of the future in the popular imagination.

In the middle of the 20th century, systematic studies of the future emerged in the shadow of the cold war, population growth, and environmental dangers. Different approaches emerged over the years, with American futurists (predictably) focusing more on short-term, applied, practical, quantitative approaches and Europeans (equally predictably) studying the long-term and the broader philosophical issues of future studies. The future was now studied in think tanks such as the Rand Corporation, the Club of Rome, and the Stanford Research Institute. American futurist Herman Kahn studied the future of thermonuclear war, and the Club of Rome published the influential *Limits to Growth* report about population growth, economic growth, and finite resources.

In the 1970s, the approach to the future took a novel turn with the emergence of scenario thinking. In the 1960's, Shell Oil found the traditional quantitative, rational approaches to long-term planning wanting. The alternative they embraced was scenario planning, which borrowed from the earlier Delphi method that used predictions from structured groups of experts. As a result of having explored several possible futures scenarios, Shell was much more prepared than other oil companies when the oil crisis and economic embargoes of the 1970s began. Rather than attempt to predict a single future based on extrapolations from the past and present, scenario thinking involves a process whereby a group of carefully chosen participants envision a number of possible scenarios for a specific company, industry, or nation. Particularly in its most advanced form, developed by the highly successful Global Business Network (GBN), the invited participants often included representatives from the arts and academia to provide a rich range of perspectives, and the process was described as both an art and a science. Scenario planning has been described by a leading practitioner as a form of social creativity (Ogilvy, 2002).

More recently along with a renewed interest in forecasting because of the enormous power of big data, there has been a shift toward embracing the saying that one cannot predict the future, but one can invent it. The pervasiveness of creativity in its many forms and expressions in today's culture also raises the question of *what* is being created, and whether what is being created is determined solely or primarily by the market economy. What is being created says a lot about the creators and what their values are, as well as about what the future will be like. As creativity reinvents lives and societies it is inescapably intertwined with larger social and ethical questions.

Utopias and Dystopias

Creativity and imagination have always played a role in the future, whether it is envisioning desirable or disastrous futures, predicting changes, or creating scenarios of possible and probable futures. Nowhere has the role of creativity and imagination been more explicit than in the creation of utopias and dystopias, ideal and nightmarish societies respectively. The first utopia was described in Plato's *Republic*, a decidedly anti-democratic vision of social order run by Philosopher-Kings. The term Utopia was first used by Thomas More as the title for his novel about an island in the South Atlantic off the coast of South America. It is telling that, as with many utopias, the book has been interpreted as a straightforward description of an ideal society, and also as a work of satire and social criticism. Even the title was ambiguous, a play on words, with the Greek *ou-topos* meaning nowhere, and *eu-topos* meaning a good place. It is characteristic of utopias that they often have deep-seated ambiguities, being at the same time a critique of the present, a vision of an alternative future, and an imaginative literary construction.

In the 21st century utopias have given way to dystopias. Already in the 20th century, such classics as Orwell's *1984* and *Animal Farm* and Aldous Huxley's *Brave New World* and *Island* warned of the dangers of mass manipulation, state control, and the use of mind-altering drugs. These themes were picked up by one of the century's most eccentric and wildly productive science fiction writers, Philip K. Dick, whose feverish, visionary novels combined a potent strain of paranoia with mysticism, mind-altering substances and dialog that often seemed straight out of a noir novel. His work has been turned into movies, producing some very successful and hard-hitting science fiction for screens small and large. It includes such dystopian classics such as *Blade Runner*, *Total Recall*, *Minority Report*, *The Adjustment Bureau*, and *The Man in the High Castle*. Dystopian fiction is now a major category both in literature and cinema. It captures a rather bleak mood, particularly among younger people, reflecting high anxiety about the environment, the economy and more generally the state of the world.

The French thinker Edgar Morin has argued that there is currently a "crisis of the future" (Morin and Kern, 1999). This crisis manifests, among other things, in the lack of desirable visions of the future and skepticism about whether there is any possibility of "better" futures. This age can be described as post-progress, because of the lack of compelling views of the future. The notion of progress, let alone of a determined, inevitable progress (e.g., every generation will earn more than their parents, technological advances always lead to improvement in quality of life), has faded, at best replaced by the term "sustainability." The Dutch futurist Fred Polak warned of the dangers of a lack of positive images of the future (Polak, 1973):

The rise and fall of images of the future precedes or accompanies the rise and fall of cultures. As long as a society's image is positive and flourishing, the flower of culture is in full bloom. Once the image begins to decay and lose its vitality, however, the culture does not long survive. (p.19)

With the lack of faith in politicians, institutions, and even in science, which is often viewed as beholden to corporate interests, there is a sense that it is increasingly difficult to talk about the future and envision "better" futures. The very notion of better futures is met with considerable skepticism, particularly by younger generations. Terms that emerged with modernity, like progress, carry too much of its conceptual baggage, suggesting a linear, deterministic movement. Already in the 20th century the horror of two

world wars broke the spell and led to a major questioning of the values and assumption of Western culture. In the 21st century a further change has occurred as young people in Europe and the United States realize that it is unlikely most of them will be economically better off than their parents and there is increasing anxiety about environmental catastrophes. In emerging powerhouse economies like China, where the last 40 years have seen perhaps the greatest and most rapid economic transformation in history, there is already an emerging questioning among younger generations of the values and benefits of consumerism and materialism.

An entirely different vocabulary and set of concepts is needed to address the complexity of the current global situation and the envisioning of alternatives. In an age when interest in creativity and imagination has reached an unprecedented degree, questions of what to create and what kind of futures humans want to create and who they want to become loom large.

The Creativity of the Future and the Future of Creativity

In postnormal times, the role of creativity and imagination is central to envisioning images of desirable futures. Without them, as Polak suggested, societies enter a steep decline. But will the same creativity of modernity be humanity's savior? This raises the interesting question of whether or not the unsustainability of modernity was a function of the way creativity was conceptualized and embodied in modernity. As modernity (and now arguably even post-modernity) are left behind, there is a recognition that there was a creativity typical of modernity, and that creativity itself is changing as culture moves into a yet unknown age (Montuori, 2011).

With the industrial revolution human ingenuity was applied to control nature for purposes of production. The industrial creativity of modernity was decontextualized with, for instance, little or no concern for the waste products coming from factories and industrial plants. Nature—society's "environment"—formed a generic context and was perceived to be so enormous and abundant that waste products could be dumped in rivers, in the air, and in oceans without ill effects. The enormous scientific, technological, and industrial creativity that fueled visions of progress and human betterment is now also viewed as a source of the current environmental crisis. This decontextualized view of creativity has ultimately proven to be unsustainable.

There are several indications that the discourse and practices of creativity are changing. The Millennial generation is made up of digital natives who have grown up in a networked, interconnected society, in an age in which the traditional image of the genius has taken some knocks. Creativity for the Millennial generation is not so much about a lone genius working in the arts or sciences, but rather about everyday, everyone, everywhere, relational creativity. When asked about creativity they are less likely to refer to remarkable individuals or "eminent creatives" and more likely to refer to the way friends and relatives did something creative together. This is paralleled by shifts in popular culture, where for instance on television such traditional figures as the lone cowboy or lone private investigator and even individual superheroes are far less prominent, while groups or tribes of heroes are increasingly popular (e.g. Marvel Avengers). In industry, collaborative creativity has taken on great importance. Innovation, a process which goes beyond an individual having a remarkable insight but extends to turning the idea into a product and getting a product to market, inevitably involves multiple participants.

There are also new approaches to creativity found in biomimicry and the concept of regenerative culture. Both are explicitly more contextual, expanding the creative process to include explicitly enriching rather than depleting or polluting the natural and social environment. Biomimicry uses nature as a source of inspiration for creativity. Regenerative culture sees humans as connected to and collaborating with nature and other human beings rather than separate from Nature. It is a systemic creativity rather than the individualistic creativity that emerged with Modernity, which viewed the individual as separate from and generally in opposition to the social and natural environment, exemplified by the image of the lone genius. Creativity in the regenerative view is part of a larger ecosystem. The larger ecosystem, meaning the total environment from which creativity emerges, is not to be exploited but regenerated. This is a very different, participatory view of creativity that in some ways harkens back to Asian views of creativity as an ongoing process in an interconnected world (Tu, 2007). This form of creativity is more contextual and collaborative, and is represented in emerging current practices designed toward creating better futures.

Uncertainty, Reinvention, and Education in a Time of Transition

The future is uncertain, and human beings generally do not respond positively to uncertainty. Neuroscientists have argued that humans crave certainty—or rather, the *feeling* of knowing and certainty. The current tendency toward polarization in public discourse in many countries across the globe is, among other things, a result of the confusion created by the current *interregnum*, this ongoing state of post-, with modernity ending but no alternative future in sight. This transition creates anxiety because it affects some key dimensions of human existence. While many names and interpretations have been given to the current transformative moment, one way to frame it is as a form of global identity crisis. An identity crisis is associated with a psychosocial moratorium, a time when new identities are explored and tried on, but also a time during which there is a goal moratorium, either an absence of goals or conflicting goals that lead to a degree of paralysis. The concept was originally applied to individuals but has also been used to explain social phenomena.

Reinvention is a trend emerging from a confluence of factors, including the self-help tradition that has long been part of American popular culture, "post-materialist" culture, and the changing and increasingly unpredictable social environment of postnormal

culture (Elliott, 2013). People are reinventing their bodies (e.g., plastic surgery and yoga), reinventing themselves (e.g., therapy, coaching, meditation), reinventing their careers, reinventing their communities both physical and virtual, and organizations are reinventing themselves to become more creative and innovative, although not necessarily less exploitative. Creativity is mobilized to recreate just about every aspect of peoples' lives.

Another parallel trend is disruption, a term used to describe the reinvention of certain industries. It has its roots in economist Joseph Schumpeter's notion of creative destruction. This is exemplified in the way such companies as Uber and Airbnb have "disrupted" the transportation and hospitality industries, challenging the traditional domination of taxis and hotels. They have disrupted the traditional ways many people get around cities and where they stay when they travel, all made possible by digital technology.

There are tensions as attempts at reinvention multiply, but also a backlash that seeks to return to a previous time, generally viewed as simpler and better. As an example, the tensions pertain to the way people in the United States reinvent:

- their bodies (with plastic surgery, yoga, living longer but also the crisis of Alzheimer's and the graying of the population, transgender and transphobia),
- their gender identities (changing gender roles, the crisis of masculinity, the myth of superwoman, LGBTQI, #metoo),
- their work identity (end of the industrial age and the loss of jobs traditionally performed by men, women and the knowledge economy, the challenges of the digital economy, the gig economy),
- their potential as human beings (the human potential movement, positive psychology, the New Age, Oprah, extreme sports, "be all that you can be," "hacking the brain," microdosing)
- their national identity (cultural anxiety, history of systematic racism, individualism, demographics and the "browning" of America, the US role in the world, new immigrants, the clash over history textbooks, diversity and pluralism),
- their existence as citizens on one planet (globalization or planetization, the threat of the new world order, the debates about cosmopolitanism, diversity, pluralism, immigration),
- their relationship to nature (the environmental crisis, organic foods, GMOs, ecopsychology, vaccines, wilderness),
- knowledge (the knowledge explosion, search engines, information overload and the need for cognitive complexity, discernment and integration, "fake news")
- their religious or spiritual identities (the sense of a quest for meaning in life beyond simply material survival (post-materialism, fundamentalism, cults, "spiritual but not religious").

This example uses the US to illustrate the notion of an identity crisis that spans from the individual to the global, and attempts at reinvention, but similar identity crises are happening in one form or other all over Europe, in China and India, both of which have experienced a tremendous transformation in the last 30 years, as well as other emerging nations like Brazil (which is the global capital of plastic surgery, or instance). One of the key factors is ever-increasing diversity, and the lack of integrative factors.

The confusion and uncertainty brought about by all these changes can lead to a form of cognitive overwhelm as well as attempts to make connections between often disparate and even unlikely data points. This also explains the enormous surge in popularity of sometimes bizarre conspiracy stories. There is a desperate effort to make sense of the postnormal complexity and uncertainty and assuage anxiety. This anxiety can lead to seeing the world in terms of either/or, with some people embracing the new directions, while others reject them and long to return to the old order.

Despite the general assumption in the scholarly literature that human beings favor certainty and reject uncertainty, creative individuals appear to have a different attitude and can see in uncertainty and complexity an opportunity to create. Unfortunately, current educational practices the majority of schools across the globe, with their focus on standardized testing, do not foster creativity or prepare students for this complex and uncertain world. In the early 1960s, psychologist Jerome Bruner argued that the main task of education was to prepare students for the unforeseeable future. Runco has likewise argued that we must prepare for an unforeseeable future, and that creativity plays a central role in dealing with uncertainty and the unforeseen (Runco, 2016). Standardized testing prepares students to deal with existing situations in pre-existing ways and respond to questions for which the answer is already known. Critics of current educational institutions see them as mired in the industrial era and still overwhelmingly authoritarian. Despite paying lip-service to the value of creativity, educational institutions have not been able to integrate creativity in a systematic way. Even at the doctoral level, the absence of creativity is evident. The main reason why over 50% of students in the United States do not complete their doctoral studies is that they are unable to become independent scholars and make an original contribution to their field (Lovitts, 2008). Creativity is key to becoming an independent scholar is, but while plagiarism is strongly discouraged, creativity is hardly ever explicitly addressed as being central to doctoral research.

Creativity is essential to the kind of mastery expected in doctoral research particularly because a Ph.D. dissertation is supposed to be an *original* contribution to one's field. Research on the phenomenology of expertise suggest that individuals who have reached the highest level of mastery—like independent scholars—do not limit themselves to analytic rationality but draw extensively on their intuition (Dreyfus and Dreyfus, 2005). Traditional education still views rationality and the rational mode of thinking as the highest goal, and it should therefore be no surprise that despite continuing efforts to promote creativity in education, education is still dominated by standardized testing and that there is a crisis of creativity in doctoral studies. Real expertise draws on intuition and while integrating rational thinking involves being able to create as well as analyze. Experts, it turns out, are able to improvise, and the concept and practice of improvisation are very relevant to the future of education, the ability to address the unforeseen and the importance of creativity (Montuori, 2003).

Improvisation and Creativity

In recent years, the phenomenon of improvisation has begun to attract attention in disciplines from neuroscience to management. Musicians have been asked to improvise while being subjected to fMRI scans, and management theorists have argued for the importance of improvisational skills in a rapidly changing, uncertain environment. Along with jazz, improvisational comedy and theater have also begun to attract attention in the management literature. The root of the word improvisation comes from the Latin *improvisus*, or “unforeseen.” Improvisers are individuals who know how to deal with the unforeseen, and they also create the unforeseen. In an art form such as jazz, musicians are judged by their ability to create an aesthetic surprise in the moment, which is also why jazz is sometimes referred to as “the sound of surprise.” A historical detour is necessary to contextualize improvisation’s resurgence.

The term improvisation has an interesting history. In widespread usage, if someone has to improvise that is often used to mean that they were unable to perform the correct procedure, that there was a breakdown of sorts, and that they somehow had to make the best of a bad situation. Something improvised was mostly considered something second-rate, make-do, remedial, because the assumption was that there was always, in the words of management theorist Frederick Taylor, “one best way.”

When jazz first emerged at the beginning of the 20th century, many mainstream critics dismissed it as music made by people who did not know how to read music, and therefore just made something up. The musical score was seen to represent music in its highest and purest form, whereas performance was considered inevitably inferior and flawed. The dominance of this perspective, coupled with a good dose of racism, did not create a welcoming environment for jazz in high culture. As Prouty stated (Prouty, 2008),

(T)he idea that European traditions were believed to be of higher artistic quality than vernacular traditions (i.e., African-American traditions) is difficult to separate from the widely held assumption that composed music (well-composed music) was of superior quality to improvised music. Thus a rejection of jazz could be seen as one manifestation of a larger rejection of improvised traditions within American musical academia (and indeed, throughout the world, at least until recently) that has long been tied to the study of the western classical canon, with emphasis upon studying and performing the music of major composers (p.2).

It is therefore interesting to note that the rejection of improvisation is actually quite recent, and that the illustrious history of improvisation in Western traditions has mostly been swept under the rug. Until about 1800, there was a considerable amount of improvisation and embellishment in performances, both by soloists, whose cadenzas were improvised and by accompanists, who often provided improvised bass lines. Many of the great composers from Beethoven to Liszt to Scarlatti were renowned improvisers, and there were even improvisation contests not unlike “cutting contests” in the jazz tradition. The change can be traced back to around 1800 with three factors, namely the development of copyright, the image of the genius composer, and the importance of symphonic music performed by large orchestras (Goehr, 1992). The music of a great composer such as Beethoven was now completely written down and copyrighted, and could not be altered in any way by the performers. Symphonies were performed by orchestras with large numbers of musicians and as a result any improvisation could quickly lead to chaos. There are clear parallels between the emergence of symphony orchestras and the economic transition to the industrial age with increasingly large factories (Attali, 1985). The symphony orchestra had to perform like a well-oiled machine, and could not tolerate deviation from the score, both because the score was written by the composer and because in such a large ensemble deviation from the score could lead to chaos. Interpretation became the main avenue for conductors and instrumentalists to express their individuality, but the notes were now all the composer’s.

Improvisation is being appreciated and recognized for its value at a time when the traditional industrial model of organization is mostly viewed as outdated, when musical copyright (and indeed the music industry) is in crisis, and the traditional image of the genius is being re-evaluated. This development also points to the way that education in general, and not just musical education, has rejected creativity and improvisation. Improvisation is the ability to create in the moment, and for improvising groups, the process is the product. Traditional industrial organization and industrial education worked in a very hierarchical, top-down manner, with a focus on control, order, and prediction. Harold Geneen, President of IIT in the 1960s and 70s captured this with his classic motto: “No surprises!” Improvisation, on the other hand, functions from quite a different set of values and premises, and can better be explained using the language of complexity. In a jazz group, the music emerges from the interactions of the individual musicians, and while there may be one leader who sets the tone for the band, leadership is also determined by who is soloing at any given point, and surprise is arguably exactly the point.

The improvisational music found in jazz represents a form of organization based on a different set of values than the ones found in post-1800 Western classical music. These values stress the role of creativity and interaction between the musicians to a much greater extent and point to new social developments and changes in the understanding of creativity. In the last 20 years, there has been a growing interest in social creativity, which includes the creative interactions of musicians and actors. The return of improvisation reflects a paradigm shift and a return to performance, breaking down traditional dualisms of modernity between theory and practice, scholars and practitioners, and rigor and imagination (Donnelly, 2016). It also points to new possibilities in education, because the challenge of creativity in education goes beyond adding the odd creativity course, but rather reframing the curriculum and the educational experience to emphasize the centrality and pervasiveness of creativity in every aspect of learning.

Social Creativity for the Future

While innovation and creativity are daily nutrients among tech titans like Google and Facebook as well as with start-ups hoping to wedge a foot in the door of a multi-billion-dollar industry, creativity is also an essential element in an emerging constellation of approaches seeking to generate alternative, better futures. Creativity is now viewed not only as the province of exceptional individuals but also more relationally and collaboratively. Public and private efforts that seek to address complex, “wicked” social and environmental issues such as poverty, the opioid crisis, global food systems, education, population ageing, and health, among others are increasingly emphasizing the importance of processes involving social creativity.

The field of social innovation provides a counterpoint to the private sector focus on innovation for profit and the bottom line. It emphasizes the need for collective innovation and creativity to address humanity’s most pressing challenges. The most well-known but also critiqued examples of social innovation include microcredit (e.g. the lending of small amounts of money at low interest to new businesses in the developing world) and “fair trade,” (e.g. producers are paid fair prices for their product such as coffee and chocolate). A criticism of social innovation is that it can inadvertently redirect attention away from dangerous structural inequalities with an emphasis on individual and group empowerment culture, which in turn is part of the neoliberal orthodoxy that promotes deregulation and liberalization. And while this might be the case in how some social innovation efforts are positioned by governments, markets, and funders, social innovation’s orienting perspective does not shy away from deep, structural change. Many social innovators are guided by an understanding of social innovation as tackling root causes, of which governance and policy are essential aspects. Within the field of social innovation, social creativity approaches are applied toward systems change (structures) as well as social change (individual and collective behaviors and mindsets).

Many processes are emerging that can support collaboration across agencies, sectors and actors to address intractable issues. Theory U, Three Horizons, Transformative Scenario Planning, Social Labs, The World System Model, and Collective Impact are all methodologies that encourage collaboration and moving the needle on big issues. Facilitation methods to support the creation of generative gatherings and dialog are on the rise including Deep Democracy, Generative Dialog, World Café, Open Space Technology, and Circle Practice (a practice that is by all means not “new” but central in Indigenous traditional around the world).

One example of social creativity in action is *The Art of Hosting Conversations That Matter*, or simply *The Art of Hosting*. The Art of Hosting is an approach to leadership that scales up from the personal to the systemic, using personal practice, dialog, facilitation and the co-creation of innovation to address complex challenges. The Art of Hosting approach provides opportunities for participatory leadership and participatory leaders, what have been referred to, in the words of Margaret Wheatley, as the activation of “leader-full” communities and organizations.

These methods of dialog are not based on a worldview that subscribes to command-and-control leadership. Rather, they intentionally invite the emergence of collective creativity that can surface through integrating and even welcoming the chaotic, complex, dynamic messiness of human behavior and interaction. The Art of Hosting is a response to the awareness that no one leader, individual, government, organization, or nation can address, never mind solve, many of our social and ecological problems. The conversational methods used support environments that promote social creativity, and stress divergence as well as convergence, conflict as well as agreement. As planet-sized problems continue to disregard nations, borders, biospheres, and disciplines, the number of approaches with the purpose of creating generative, life-affirming futures continues to grow, and the challenge to mobilize creativity for better futures becomes ever greater.

Conclusion

Creativity changes the world and shapes the future, but creativity itself is in turn being shaped by the challenges of an emerging future. The creativity of modernity achieved tremendous advances and led to a great transformation and what we now think of as the modern world. At the dawn of the 21st century, the current crises—or rather the interconnected poly-crises—are leading to different understandings and practices of creativity: more contextual, relational, and deeply interwoven with social and ethical concerns. As the fascination with creativity in all aspects of society blossoms, there is an awareness that with greater creativity comes greater responsibility.

Glossary

Art bias A common mistake where creativity is thought to occur only in art. The corollary, equally mistaken, is that only artistically talented individuals are creative.

Complex A concept that is often used in clinical psychology and psychiatry to describe systems of interrelated characteristics that covary and are related to a particular psychopathology.

Disappearance of the problem Someone becomes so interested in solving a problem that it is transformed into a gratifying challenge and the person no longer views it as a problem.

Parsimony A guiding principle of modern science which emphasizes simplicity of explanation. All other things being equal, the simple explanation is best.

Syndrome A set of symptoms or indicators, often used to define or predict disorders or behavioral tendencies, and sometimes used to describe the creativity complex.

Introduction

Creativity has only been recognized as a fitting topic of scientific study for perhaps 60 years. There were several systematic investigations well before that – including Catherine Patrick's series of studies with artists and scientists in the 1930s – but archival analyses of publications and citations on the topic of creativity show that empirical work was sparse until the 1960s. There were several reasons for this. One is that creativity was (and often still is) equated with art. That in turn ties creativity to aesthetics and subjective processes that most scientists assume preclude rigorous science and best belong in the qualitative or nonempirical domain. The assumption that creativity is always tied to art is still quite common and has been called an *art bias*. It is especially problematic in education because it may lead teachers to assume that only students with clear artistic talents are creative. An educator who holds the art bias may not look for creativity in other students.

A second reason creativity was excluded from the behavioral sciences for so long is that it has varied etiology and is expressed in so many different forms and media. Studies of its etiology indicate that creativity is influenced by personality, cognitive and extracognitive processes, settings and culture, development, mood, attitude, affect, Zeitgeist, and perhaps even luck or chance. Its expression is at least as varied and includes all of the arts, but also technology, innovation, entrepreneurship, invention, and diverse sorts of problem solving. No wonder creativity has been defined, almost from the beginning, as a 'complex' or 'syndrome.'

This article reviews theories which explicitly define creativity as a complex. It also examines their assumptions and contrasts the definition of a complex with the opposite view, namely the *parsimonious theory of creativity*. Coverage is probably broader than may be suggested by the label *creativity complex*. That is because the creativity complex often goes by other names. *Creativity syndrome* was used in 1965 by Donald MacKinnon, a key figure in the early research done at the *Institute of Personality Assessment and Research*, and by Michael Mumford and Sigrid Gustafson in their influential article from 1988 in the *Psychological Bulletin*. Mumford and Gustafson also referred to *multivariate perspectives* on creativity. Then there is the idea of a *multilevel theory* of creativity. This is an attempt to emphasize the fact that creativity is often influenced by the individual, the immediate setting, and the general culture (be it organizational, geographical, or both). As we shall see when the advantages and disadvantages of the definition of creativity as complex are reviewed, the best label for the complex may be *multivariate*. That covers all of the different theories that explicitly describe the

variety of influences and expressions of creativity, and it avoids unwanted connotations. More will be said about this below, after the facets of the complex are explored.

Defining Creativity

The research on creativity certainly does point to a large number of influences and correlates, some personal (e.g., affect, cognition, personality), some environmental (e.g., setting and resources), and some cultural (e.g., values and expectations) and interpersonal (e.g., encouragement and support). The idea of a complex recognizes each but also allows for diversity of expression, which is quite important given the differences among domains of creative endeavor and differences among kinds and levels of creative performance. Creativity can be expressed by a child, using his or her imagination, for example, but it can also be used by world-class experts when solving highly technical or far-reaching social problems. In slightly different terms, creative talent is often apparent in the lives of eminent persons, but 'everyday creativity' also allows each of us to deal with the hassles and surprises of our existence. In both cases original and effective ideas are used, so both qualify as creative behavior. The point is that creativity is complex both in terms of the antecedents and causal factors and also in its expression and the outcomes.

As a matter of fact the complexity of creativity is apparent even if the focus is on one particular creative event or product and not only when its diverse expressions are examined. That is because all creative things, be they inventions, innovations, works of art, scientific breakthroughs, or original solutions to everyday problems, share more than one attribute. There is one primary attribute, which is originality. All creative things are novel, unusual, unique, or in some fashion original. Originality is necessary but not sufficient for creativity. It is not sufficient for creativity because original things are sometimes not creative. Something may be original but useless, unrealistic, or ineffective. This is where the third kind of complexity comes in (to go along with its complex etiology and diverse expression): creative things are, at a minimum, both original and effective. Further, each of these two attributes can be defined in more than one fashion! An original thing might be entirely unique, for example, or it might be merely highly unusual. Even more to the point, the effectiveness of creative things may be determined in numerous ways. In the case of creative solutions to problems, effectiveness is supported by the fact that the creative solution actually solves the problem. But not all creativity involves problem solving. In the arts the effectiveness of creative things is typically aesthetic rather than purely functional. Along the same lines, creative art may be produced to express oneself rather than to solve a problem. Admittedly artists sometimes have problems finding the best ways to express themselves, in which case art could be seen as problem solving. Conversely, someone may be so interested in solving a problem that it is transformed into an enjoyable challenge and the person no longer views it as a problem. This has been called *the disappearance of the problem*.

Some definitions of creativity include a social component. The assumption is that things or people are only creative if an audience attributes creativity to them. Although many domains do in fact rely on audiences and social judgment, at least at the highest levels, there are serious problems with any definition that requires social attributions. It would, for example, exclude many everyday creative efforts, and these may by far constitute the largest of domain of creative expression. The idea of everyday creativity implies that creativity is a part of every person's life, everyday, rather than only being a part of the lives of professional creators or famous people. A social requirement would also exclude children's creativity, at least if it assumes that creative things must be original when compared to social norms and standards. Children may be original, in play or imagination, but much of what they do is original only on a personal level and not if compared to what others have done.

The real problem with a social requirement in the definition of creativity is that it confuses creation with judgment or reaction. To require that all creative things elicit social attributions would be a bit like saying that the speed of a runner depends on the stopwatch or accuracy of a timer. For the scientific study of creativity, it is best to keep creation separate from reception and from possible attributions. Those come after creation has taken place. For this reason the list of influences given below to exemplify creativity as a complex focuses on individual factors, such as cognitive talent or personality. It excludes social and cultural influences. These may actually influence creative efforts, especially if you consider that creative potentials are probably not developed unless they are valued by the culture and society in which they are expressed. Still, the focus here is on personal and intrapersonal influences and excludes social influences. Those could be addressed in a discussion of social judgments or audiences, where the focus is reaction not creation.

Creativity would be even more complex if social attributions were included in its definition, but any such definition would conflate creativity with fame, reputation, and impact (Runco, 1995). Quite a few social and cultural influences, including those experienced in the home, school, or work setting, are detailed elsewhere in this encyclopedia.

Diverse Influences on and Expressions of Creativity

The view that creativity is a syndrome or complex is justified by the fact that there are diverse influences on its development, diverse forms and media of expression, and more than one required indicator or criterion needed to identify creative things. Several criteria (originality and effectiveness) were mentioned above. Examples of the diverse influence and diverse forms of expression are equally easy to find. Several different kinds of cognitive capacity and skill have, for example, been associated with creative thinking. Creative thinking may involve imagination and insightfulness, for example, as well as a tendency towards divergent thought. Divergent thinking in turn is usually operationalized in terms of several kinds of ideation, including fluency, flexibility, and originality. Creativity seems to benefit from metacognitive processes as well, such as an intentional attempt to shift one's perspective or to put a problem aside to allow incubation.

Diverse cognitive influences on creative thought are also apparent in stage theories of the creative process. Wallas' four-stage model is the best known of these, though presented long ago (*The Art of Thought*, 1926). It includes preparation, incubation, illumination, and verification. More recent renditions include an implementation stage, which makes sense if the emphasis is on innovation or practical applications of creative thinking. A two-tiered model of the creative process includes many of the same stages but views preparation as a kind of problem finding. It divides this into problem identification and problem definition, which of course adds complexity. There is also an ideation stage, which is divided into those same tendencies mentioned above (fluency, originality, flexibility), and an evaluation stage, which may be divided into *valuation* and *evaluation* (the former being appreciative, the latter critical) and into inter- and intrapersonal judgments. The two-tier process model also recognizes the potential impact of knowledge and motivation, and as you might expect divides each of these into specifics. The former includes procedural and declarative (or conceptual) knowledge, and the latter includes intrinsic and extrinsic motives.

Various *cognitive styles* have been associated with creative thinking. There is, for example, empirical data distinguishing assimilator, innovator, adaptor, and explorer styles, just to name some of the more commonly used. Even the long-standing style theory that contrasts deliberate with impulsive cognitive tendencies has been associated with creative thinking. The theory of creative styles is especially relevant because it assumes that there is more than one way to be creative. Unlike theories of ability, which frequently assume that there is one dimension and that people either have a high or low level of that one ability, theories of style agree that there are different paths to behaving creatively. The focus in theories of creative and cognitive style are on "how" rather than "how much."

Complexity is further suggested by the fact that creative thinking differs with the domain or subject matter. Creative thought can draw on verbal skills, but it may also rely on imagery, preverbal processes, and 'preinventive forms.' Because many of these differences in the mode of thought can be understood as domain differences, more will be said about them below, in the section on diverse expressions of creativity. At this point it should be clear that, even within the cognitive category of influences, there are numerous possibilities. The concept of a complex thus makes sense.

The same is true when considering the influence of personality on creative efforts. The most important personality traits for creativity seem to be openness, autonomy, wide interests, flexibility, and intrinsic motivation. The last of these suggests that there are motivational and therefore affective bases to creativity. Plenty of research indicates that mood influences the thinking tendencies that support or inhibit the likelihood of finding original insights. And it is not a simple thing: on some tasks it seems to be helpful to be elated or happy. This can lead directly to an appreciation of a wide range of options and new possibilities. But some tasks seem to benefit from the darker moods.

Attitudes also play a role in creative efforts. Again, there are a number of different possibilities, including openness to divergence – which fits well with theories of divergent thinking – playfulness, and tolerance. There are also attitudes which most likely inhibit creative behavior, including tendencies towards *satisficing* or premature closure. Note here the idea that there are supports for creativity as well as probable inhibitors. This same dichotomy applies to virtually all influences, be they cognitive, personality, attitudinal, affective, or whatever. It may not literally double the complexity of creativity, but it certainly does dramatically increase the range of influences.

The diverse expressions of creativity, which also help explain why it is viewed as a complex, are very easy to summarize. Much of the early research on creativity – including that mentioned above and conducted at the *Institute for Personality Assessment and Research* – involved writers, architects, and other professional groups, and data supported the idea that the requirements for creativity differ from group to group (and domain to domain). Howard Gardner's theory may be the most formalized delineation of domains. It includes verbal, mathematical, spatial, bodily-kinesthetic, intrapersonal, interpersonal, musical, and naturalistic domains. Gardner argued convincingly that these differ from one another in their biological, developmental, and cognitive bases. His is not a theory just of creativity but subsequent research with creative samples has largely supported the same set of domains.

Subdomains are also described in the creativity literature, and they too imply that creative talents can be expressed in diverse ways. Even in an area such as language there are differences between poetry, drama, novels, speeches, lyrics, jokes, political spin, and oral communication, just to name a sample of what might be called verbal subdomains. The various sciences also differ, especially if the hard sciences are contrasted with the social sciences. Ask any scientist and they will probably be able to point to numerous idiosyncrasies of their particular field. Then there are the different possible expressions of creativity at different ages, as implied by what was said above about children's creativity. Add to that the "old age style" of highly creative artists and the expressions of creativity late in life.

One of the clearest examples of diverse expressions of creativity are those identified in the work on creativity in the moral domain, which includes both humane and benevolent creativity but also, at the opposite extreme, malevolent creativity and the "dark side". This work is especially interesting because the dark side is currently so obvious in the political realm (at least since November 2016) and has such broad implications (e.g., debates about the climate crisis which include arguments that have no basis in fact but are clearly politically motivated). Studies of benevolent and malevolent creativity point to the significant role played by intentions (Runco, 1993), but what is most relevant here is that creativity in the moral domain covers the full range, from benevolent to the opposite, the malevolent.

Although there is a bit of discussion in the creativity research about the possibility that there is a commonality among domains and all possible expressions (i.e., a kind of "general factor" underlying all creativity), that would not really eliminate the obvious fact that creativity takes many forms. At most, if a commonality is uncovered, it would mean that there are both similarities and differences among domains and the possible expressions of creativity. Thus, given its etiology (e.g., the influences mentioned above), the multiple criteria used to define it, and its varied expression, it is easy to see why it is so common to view creativity as a complex.

Parsimonious Creativity

The definition of creativity as a complex is consistent with much of the research on the topic and has a number of advantages. It applies very broadly, for example, as is apparent in the long list of influences and diverse domains of expression mentioned just above. Yet there are also disadvantages. One is suggested by the connection of 'complex' and 'syndrome' to psychopathology. These two labels are in some ways applicable to creativity—they both imply that there is a set or system of relevant symptoms and indicators – but those same labels frequently connote psychopathology. Given misconceptions of the association of creativity with psychopathology (e.g., the creator as 'mad genius' or necessarily bipolar or suicidal), this is a potential disadvantage. That is one reason why earlier I suggested that it may be best to view creativity as *multivariate* in its etiology and expression. That label allows for a set of indicators but does not have the same connotations as *complex* or *syndrome*.

A second concern with the creativity complex is more significant. This reflects what is inherent in any complex: it is complicated. More to the point, it is not *parsimonious*. Parsimony is an important part of all sciences. It requires simplicity of explanation. All other things being equal, the simple explanation is best. Is a parsimonious definition of creativity possible? To define creativity in this fashion, there must be something common to all creativity.

It may be difficult to see what is common to all creativity, given all of the various influences and diverse expressions (e.g., domains and differences at different ages). Perhaps a commonality can be found if one step is taken at a time, to narrow the field and remove each unnecessary part of the complex in a systematic fashion.

The first step towards parsimony is dictated by the scientific concern for *causality*. Without a doubt, at the heart of all scientific theories is an interest in uncovering actual explanations for events and actions. Good science does not merely describe; it also explains, and a good explanation must identify specific causal factors. This is why experimental research is so highly respected: it eliminates confounding factors and nuisance variables so true causes can be unambiguously tied to effects. A parsimonious theory of creativity should focus on explanations rather than descriptions. It must identify causes, or what are sometimes referred to as the mechanisms that are responsible for creativity.

Thus the first step towards simplifying the complex involves eliminating effects of creativity from its definition. These may be interesting, and socially or personally useful, but they are not causes and not really explanatory. A great deal of the creativity literature describes effects, and all of those findings can be eliminated for a parsimonious definition. Effects are on the wrong side of the causal equation and thus do not advance the parsimonious theory of creativity. Certainly causes can sometimes be inferred from effects, but it may not be necessary to resort to such inferences.

As a matter of fact, many of things that make creativity seem complex are effects of creative processes. As such they make themselves known only after creativity has occurred! Recall here that social definitions of creativity were dismissed above because they are reactive and not a part of the actual creation (i.e., when something new and useful is brought into existence). Other effects and results include the products which are so often studied in creativity research. They too can be put aside since they do not offer direct information about causality. Creative products are original and useful, and they may be highly desirable, but they do not explain creativity. They are results or outcomes, not causes. They cannot be manipulated to control the creative process, and any theory based on them is post hoc and much more descriptive than explanatory. It will also lack generality, given that many creative experiences do not lead to a lasting product. Think here about how reputations and judgments of creativity change, especially over long periods of time (Runco et al., 2010; Runco et al., 2016).

A second but more difficult step towards parsimony involves putting aside all 'mere influences' on creativity. Influences can be dismissed because they offer no guarantees. They are not really determinants. Influences may have some impact, but that is not the same thing as being causally required. Mere influences are much weaker than actual causes, much less reliable, and insufficient as scientific explanations. Think back on the influences reviewed above, when the theory of a creativity complex was being outlined. Consider each of these individually and ask, does all creativity depend on this influence? Does all creativity depend on, say, intrinsic motivation? It does not; there are many cases where extrinsic incentives are involved. Is all creativity a result of a particular mood, or even dependent on a particular cognitive process? Far from it: for some tasks, one mood seems to be best, while for others, another mood is conducive to creativity. Or it may be that the most supportive mood varies from stage to stage of the creative process. The same thing can be said about cognitive processes. In fact it can be said about all potential influences. They do not apply all of the time.

Creativity can be defined parsimoniously if it includes only what is always vital and necessary. All else is extraneous. This allows us to exclude even more than products, effects, outcomes, and results of the creative process. The literature on influences probably constitutes the largest portion of creativity studies. And like the research on products, it is useful. It may suggest how to make creative activity more likely, for some people, some tasks, some of the time. But a parsimonious definition of creativity includes only what is necessary, not just what is sometimes influential. A parsimonious definition excludes outcomes because they occur after the actual creation, and it excludes mere influences because they are not always involved, and thus not vital, as would be expected for a causal explanation.

There really is very little that is vital and necessary for all creativity. In fact, the only things that are universal and necessary were mentioned above. They are (a) originality and (b) effectiveness. Granted, there is variation in the wording. Sometimes originality is labeled novelty, for example, and sometimes effectiveness is labeled adaptiveness, fit, utility, or appropriateness. Whatever the label, originality and effectiveness are vital for all creativity. This is not all that constraining, either. Originality and effectiveness apply to

all domains and all categories of research. Thus (a) creative products are original and useful; (b) creative persons have the capacity to be original and find or produce useful things; (c) creative places are those that support the production of original and useful things; and (d) the creative process is apparent when a person is progressing towards something that is original and useful.

The objective of a parsimonious theory is to keep things as simple as possible. That does not necessarily mean that everything is removed and excluded, one by one, until only one causal factor remains. Obviously the epitome of parsimony would be a theory which points to one causal factor that explains everything. But parsimony can be taken too far, in which case it loses its value. If too much is removed, just for the sake of simplicity, accuracy and understanding are lost and parsimony has done science a disservice. Even though the method used here, which excluded influences and factors which do not apply to all creativity, only reduced the list to two requirements, originality and effectiveness, this may be the best we can do. It may not be possible to distill theories any further, at least if we wish to accurately understand true creativity. But a two-factor theory of creativity is much more parsimonious than those relying on the idea of a creativity complex.

Conclusions

The idea of a creativity complex is in some ways useful. It suggests that original and effective behavior in diverse domains can all be considered under the general umbrella, 'creativity.' It offers breadth. It is good that we see creativity in various domains and appreciate the diverse expressions of creativity.

There are, however, several problems with the idea of complex. One is just semantic – the connotations of the labels complex or syndrome. The other is much more significant. It implies that studies of creativity are still not entirely scientific. After all, the sciences focus on causality and value parsimony, and the creativity complex is nearly the opposite of parsimonious and includes many things that offer little or no causal information.

The scientific requirement of parsimony is usually taken to mean that, when there are various explanations for some phenomenon, the simplest one is best. That in turn supports the parsimonious theory of creativity which only includes originality and effectiveness. Parsimony requires that everything that is not vital is excluded. This really just means that the creativity complex can be simplified if the focus is on that which is involved in all creativity, not just involved in some creative things.

The idea of a complex would seem to be untenable according to the primary goals of science, which are prediction and control. These two things, prediction and control, were used by B. F. Skinner as standards of rigorous science. Think of the numerous important benefits of creativity if it could be accurately predicted and controlled. Those make the parsimonious approach to creativity all that more attractive.

Introduction

Parallel to increasing importance of innovation economy and accelerating speed of change, public interest in creativity has also increased. As of December 2018, the most popular TED talk is about creativity (Robinson, 2006), which inquired how schools influence creativity. Newsweek and Time magazines released special reports on creativity and explored the reasons behind cross-generational declines (Bronson and Merryman, 2010) as well as the means to enhance it (Time, 2018). A common theme across various popular talks on creativity is that everybody has creative potential and creativity is an important asset to individuals and for society. Failure to fulfill one's creativity is a loss at both levels. The argument follows as such: if everybody possesses creativity, why are some people more creatively accomplished than others? What prevents a full-expression of creative capacity?

The concept of creativity gap is central to these questions. The *creativity gap* refers to the level at which one underutilizes his or her creative potential. To understand one's creativity gap, it is important to look into creative potential that is yet to be actualized and the actualized creativity. The sum of the two would be a perfect transformation of creative potential into creative performance, which would reflect an ideal state where people reach to the full potential of their creativity. In reality, the former may be higher than the latter, reflecting the least ideal state compared to the other way around, at which people actualize their creative potential to some degree but there is still more to fulfill.

Creativity Gap as the Discrepancy Between Creative Potential Versus Creative Performance

Conceptually, the most relevant connection to the creativity gap is the distinction between creative potential and creative performance (Hinton, 1968). Creative potential refers to the skills, abilities, and attitudes that lead to creative behavior whereas creative performance is the actual creative output. Creativity gap increases as the proportion of creative performance to creative potential decreases. This distinction has implications for the measurement of creativity as well. Measuring creative achievement seems to be more objective and easier to capture through testing than measurement of creative potential which is more elusive and inclusive of multiple constructs. However, focusing on the measurement of creative potential may preferable to measuring creative achievement because creative potential may be less influenced by societal factors including socio-economic status than the creative achievement. Measuring both would help reveal creativity gap by identifying the points of discrepancy.

Mark Runco (2003, 2004) has used this distinction quite often and argued that education should focus on creative potential because creative performance requires more than creativity itself (e.g., social expression and recognition). A person is still creative when a creative idea has not been transformed to creative outcome or when a creative outcome has not been validated by others yet. Creative performance is influenced by additional factors such as chance, socio-economic status, and resources. Presence of such additional factors may conceal the essential quality in the creative process that is the creative potential and the educators should pay more attention to this essential quality. This logic is consistent with his emphasis in "personal creativity" which is different than "socially recognized creativity". The personal creativity often focuses on *process* whereas socially recognized creativity focuses on the *product*. Personal insights and interpretations are considered part of personal creativity whereas a finalized outcome is at the core of socially recognized creativity.

As stated above, creative potential is crucial for personal fulfillment. Nevertheless, it is difficult to define conceptually and to observe empirically. To complicate things further, another distinction was made between creative potential and practiced creativity (DiLiello and Houghton, 2008). The latter focuses on the *perceived* opportunities to utilize creative skills and abilities on a specific task. Creativity is associated with thinking without limits, whereas almost any organization in the world, be it a school, government office or private corporation, has some kind of structure that imposes certain limitations to those in the organization. Creative people may often feel confined and repressed when their talents are not channeled, expressed, and challenged. When one believes

creativity is not expected or desired, he or she is less likely to engage in a creative behavior (Ford, 1996; Tierney and Farmer, 2002; Farmer et al., 2003). This difference is important because creativity gap may emerge at a personal level when a person starts noticing the lack of means for practicing what he or she possesses.

The word “perception” is critical in practiced creativity and is subjective. Indeed, the same environment may be perceived as conducive to creativity for one person but not for another. Yet, to some degree such perceptions are rooted in the characteristics in the environment. Feelings of restrictedness or confinement are more likely to occur when the work or school climate is not supportive of creative characteristics than not. Therefore, there are ways to reduce creativity gap that is related to the perceptions of the individuals, which will be discussed in a later section.

The concept of creativity gap is directly related to some key concepts in humanistic psychology. Broadly speaking, elimination of the creativity gap implies becoming a self-actualized person, in Maslow's (1974) terms [see Self Actualization, this volume]. His thoughts on creativity seems to reflect the distinction between creative potential and the creative performance. Maslow himself distinguished *self-actualizing (SA) creativeness* from *special talent creativeness*. SA creativeness is about creative personality rather than its achievements. It consists of many personality-related qualities such as freedom, courage, and spontaneity that permeates all aspects of life rather than serving as a problem-solving or product-development tool alone. Therefore, SA creativeness is more about “Being” and “Doing” and the creativity gap is about overcoming barriers for such a person to come into Being.

Creativity Gap as the Discrepancy Between Formal Versus Informal Settings

Another way to look at the creativity gap is to compare creativity as demonstrated at formal versus informal settings. As discussed above, schools or workplaces may be confining to the individuals with a high level of creative potential as a result of rules, procedures, bureaucracy, protocols, lacking resources and time, the nature of goals and priorities determined for the organization, the emphasis in efficiency and productivity, or organizational culture and tradition. Therefore, individuals may feel like they have to comply with the organizational expectations rather than influencing the organizational culture to make a space for their personal expression of creativity. According to Adobe's 2012 Global Survey of Creativity with approximately 5000 adults in the developed countries, only one in four people believe they can actualize their creative potential although more than two-thirds believe creativity is critical to economic growth and its value for the society. They think productivity is more desirable than creativity at work and most think that schools suppress creativity. Therefore, highly structured environments such as most workplaces or schools may not be the best setting for observing personal creativity. Natural expression of creativity more likely to appear in informal settings where people are in control of their time and resources.

Observing creativity demonstrated at formal settings such as the workplace or school versus informal settings such as at home, interest or hobby groups, or vacation is another way to get at the creativity gap. People can resort to their creativity at informal settings that they are unable to use in the formal settings. Therefore, comparing creative activity inside and outside the workplace or school may capture the creativity gap. This is how Mark Runco et al. (2017) operationalized the creativity gap in the school context. This study is built on the earlier work by John L. Holland (1961) who found that academic achievement and creative performance are largely unrelated because factors leading to the two differ from each other. Academic achievers tend to be serious, responsible, rigid, persistent on their goals, conforming to the rules and expectations. They tend to have authoritarian parents and be more favorable to the teachers (Holland, 1959). Creative people tend to be original, independent, and open to experiences and their parents are more permissive. Holland's later work (Holland and Richards, 1965) also found that academic and non-academic (extracurricular) accomplishment is independent of each other. Extracurricular accomplishment consists of different forms of creative activity such as drama, science, arts, or business. Academic achievers and creative achievers tend to be different people or being a high achiever in one does not imply being a higher achiever on the other. This may explain why some garage entrepreneurs are not high academic achievers (a.k.a. the garage belief). As a result, Holland argued that most traditional schools may hinder, rather than support, creativity. Then, a garage is an example of informal, unstructured setting where creativity is put into practice without many of the external constraints on personal expression of creative potential.

Runco et al. (2017) revisited Holland's findings after 50 years. They asked the college students to indicate their creative activities and accomplishments as demonstrated inside versus outside the school. Similar to Holland's findings, the relationship between the two is mostly small or negligible. Moreover, creativity activity was significantly higher outside the school than inside the school. They went further and explored the reasons behind this creativity gap. They regressed that creative activity outside the school on creative activity inside the school to obtain the creativity gap. Next, they explored several predictors to explain the variation in creativity gap and found that creativity gap tends to be higher for those who have positive attitudes and values toward creativity, higher creative personality, and prefer working in solitary rather with others. These results are eye-opening because restrictions in the formal settings are more likely to limit those who have greater creative potential than others. Consequently, creativity gap seems like a bigger threat to them.

Creativity Gap as a Failure to Commercialize Ideas That Can Be Commercialized

Creativity has much to do with ideas. Any creative product or outcome was once seeded as an idea. Generation of an idea, noticing the potential in it, and the implementation are different processes. A successful creative process includes all of these steps to be attended. There may be situations, in which a creative idea is generated but not noticed or implemented. According to Maksim

Belitski and Sameeksha Desai (2016), creativity gap emerges when a greater (more selective) creativity filter is used to choose ideas to turn to product. Creativity filter refers to the decision-making mechanisms that select certain ideas over others to commercialize under uncertainty. So, the ideas that deserve to commercialize, but are not, lead to a creativity gap. The higher the difference between actualized commercialization of creative ideas and potential ideas to commercialize, the larger the creativity gap.

The decision to commercialize a creative idea is an important step and this may be the key factor to successful start-ups. According to Robert Sternberg and Todd Lubart's (1991) Investment Theory, creative people are good at recognizing and investing in creative ideas. Those people tend to "buy low and sell high". They identify the potential promising ideas that are not recognized by others (i.e., buy low) and improve and refine them to enhance their usefulness and marketability to others (i.e., sell high). This theoretical perspective may be considered along with Csikszentmihalyi's (2014) Systems Theory, in which creativity of an idea is facilitated and compromised by the field and the domain. Although, some people are better "investors" than others, the final success of a creative idea requires factors outside of the individual. The investment capability is complemented by other key players or gatekeepers in the field who determines what ideas have a promise. Putting these two theories together, creativity gap related to the failure to commercialize an idea may be attributed to both personal and environmental factors. Some people and contexts are more open to creative ideas than others and this openness reduces the creativity gap. According to Belitski and Desai, creativity gap (so, creativity filter) diminishes with more entrepreneurship. More entrepreneurship means more ideas to test out and more risk-taking on potential ideas. As more ideas are tested and commercialized, the probability of "false negatives" (i.e., failure to detect a promising idea) is reduced. A possible negative consequence of this is higher rate of failed start-ups—the investments that do not bring returns. Because of over-inclusive selection, the "false positives" (the selection of ideas should not have been selected) will also increase.

Belitski and Desai found that entrepreneurship (the density of start-ups) moderates the relationship between creativity (the proportion of the creative sectors) and urban economic development. In other words, existence of start-ups facilitates those in the creative sectors to contribute to the economic development. Those start-ups reduce the creativity gap by providing an outlet for the creative people to transform their potential into performance.

The Creativity Gap as the Discrepancy Between the Perceived Value of Creativity Versus Commitment to Creativity

Some researchers used the term "creativity gap" to describe the inconsistency between the perceived value of creativity and commitment to it. The value of creative thinking is obvious to so many, however, acknowledging its importance does not always follow actions to prioritize it in the workplace or schools. After all, creative thinking involves risk-taking, change in habits, delay of gratification, and tolerating ambiguity and these are viewed as luxurious for some people or organizations. This kind of creative gap refers to the distance between where most organizations are and where they want to be. This disparity between the reality and vision is observed in different sectors such as healthcare and education. For example, PricewaterhouseCoopers' (PwC) Annual Global CEO Survey revealed that 79% of the corporate executives believe innovation leads to higher revenues with increasing efficiency and superior growth whereas active investment in innovation does not follow closely.

Matthew Makel (2009) points out this kind of creativity gap in education. Creativity is highly praised and valued by many educators but it is mostly absent in the classroom. He suggested that changes are needed in educational policy, societal values toward creativity, teacher training, creativity researchers' level of engagement in educational practice, advocacy projects, and change in language that emphasizes the need for encouragement of creativity rather than enhancement of it. He highlights the importance of preparing the youth for the creative age where transmission of the information is less important than the way it is used. According to Makel, the strategies to close the creativity gap in education includes eliminating the difference in the context of learning and application. When the context of learning and application differ from each other, students may not be able to transfer the learning to a new context. He also criticizes the current educational policy for lacking a creative pedagogy and overemphasis in standardized testing. Another problem with this approach is that it prioritizes the short-term gains (success on tests) rather than long-term goals such as developing students' creative thinking. He argues that this system may penalize teachers who prioritize creativity development.

The difference between the value of creativity and commitment to it may also stem from the limited understanding of the concept of creativity or misconceptions around it. Although creativity is a positive quality for many people, some traits of creative individuals may be hard to manage or tolerate in the classroom context at least for some teachers. Those characteristics include independence in thinking and behavior, challenging the authority and status quo and autonomy. Students with these traits may easily be perceived as disruptive and annoying. This is why John Holland (1959) warned about teacher ratings as a questionable predictor of creativity. More recently, Erik L. Westby and V. L. Dawson (1995) found that teachers' favorite students may not be the creative ones and those who display creative characteristics may not be welcome by them. Christina L. Scott (1999) compared teachers and college students' perceptions of creative students and they found that teachers are more likely to find creative students as potentially more disruptive than the college students. She argued that there may be a bias against the creative students in the classroom as they have difficulty in following the rule and showing compliant behaviors.

Bias against creativity is not limited to teachers or education. Jennifer S. Mueller, Shimul Melwani, and Jack A. Goncalo (2012) explored why some people tend to reject creative ideas even though they indicate creativity as a desirable thing. They found that people tend to prefer practicality over creativity during the times of uncertainty. They argue that the bias against creativity is an implicit one and may prevent a person from recognizing the potentially creative ideas. In later research, Jennifer S. Mueller et al. (2011) found that those who suggest creative ideas are less likely to be perceived as having leadership potential unless the person

suggesting them is a charismatic leader. [Young Soo Lee et al. \(2017\)](#) investigated the emotional reasons behind the implicit bias against creativity and found that people experience fear when there is a highly uncertain situation and tend to rate an idea as less creative than low-uncertainty situations that trigger happiness or anger.

Creativity Gap as Differences Across Regions and Cultures

Creativity may be expressed more in some places than others. The differences in the expression of creativity may occur factors beyond the individual such as cultural values, parenting, educational system, and opportunities and resources available. [Yong Zhao \(2008\)](#) used the concept of “creativity gap” to describe American superiority in creativity over Chinese and explained the difference in terms of collectivist values that demand conformity, parenting practices that overemphasize external standards of academic success, and standardized and centralized educational system that leave little room for flexibility around the established norms and rules.

The same line of reasoning may be extended to different regions of the same country or a particular cultural group. [Cynthia Negrey and Stephen D. Rausch \(2009\)](#) used the term “creativity gap” to describe regional differences in creativity across different parts in the United States. Their work relies on [Richard Florida’s \(2002\)](#) work on the Creative Class. Florida argues that creativity is the key to economic development and those who belong to the creative class are the ones who use their mind rather than their physical capacity. They develop intellectual products rather than physical products. Creative places are those that more of people in the creative class live. He argues that creative people are drawn to the places like that. Other major three characteristics of the creative cities include technology, talent (proportion of educated people), and tolerance (openness to diversity). Based on these factors, Florida identified the most and least creative cities across the US cities.

Florida’s work was criticized for ignoring socio-economic factors, which was also found to be influential on creativity. [David Yun Dai and his colleagues \(2012\)](#) defined the creativity gap as differences in creativity led by socio-economic status (SES). They found that socio-economic status (SES) and parental education explain part of the discrepancy in creativity. Students of the high SES families and educated parents performed higher than low-SES families and less educated parents.

Creativity Gap as Temporal Differences

Creativity does not follow a linear pathway according to some research. Some periods in history witness more creativity than others. Using [Urie Bronfenbrenner’s \(1994\)](#) terminology, the chronosystem may lead to the creativity gap. [Berys Gaut \(2010\)](#) refers to creativity gap as such temporal changes across ages and explain improvements over time as a result of the increasing population density that lead to better preservation of creative outcomes. [Dean Keith Simonton’s \(1975\)](#) historiometric studies also reveal some of the mechanisms underlying greater creative activity. He found that creative development is positively influenced by role model availability, political fragmentation, and revolutions or revolts and negatively influenced by political instability.

Closing the Creativity Gap

The above discussion on creativity gap alluded to some of the factors leading to it. Some of these factors are internal and some are external. Internal factors include attitudes and values toward creativity, implicit bias against creativity, limited understanding of creativity, self-imposed constraints, personal mindset, conventionalism and conservatism as opposed to openness, and avoidance from uncertainty and risk. External factors consist of cultural values that prioritize social approval and expectations, conformity, social norms, rules and regulations, bureaucracy, SES, and lack of time, resources, and opportunities.

Those factors also provide clues about the ways and strategies to close the creativity gap. Broadly speaking, any intervention or condition that allows and encourages creative expression helps to close the creativity gap. The training programs that develop personal awareness and knowledge on creativity, emphasize attitudes and values that support creativity, explore personal habits, blocks, and self-imposed constraints are particularly important for closing the creativity gap. Such programs may be viewed as a way to recapture creative potential that tends to disappear with aging, certain educational practices, environmental restrictions, and social expectations.

Environmental restrictions may also be overcome through effective leadership. As [Trudy DiLiello et al. \(2011\)](#) indicated, one way to reduce the creativity gap is to change the perception of environmental support. They found that those people who have high creative self-efficacy and perceive support for creative behaviors are more likely to engage in creative activity than those who do not perceive such support. Creative potential is more likely to translate to creative outcome when support and encouragement are offered.

Closing the creativity gap may be easier now than the past because of technological advancements and available resources and opportunities. Technology removes many of the existing barriers against creativity by allowing faster exchange of knowledge and greater network among the experts and creative agents. Computer and internet technology, more specifically, social media have become a major source of inspiration and knowledge dissemination. Through technology, people may keep up with the most recent developments and build on the existing knowledge and elsewhere.

Creativity benefits from resources and opportunities. Lack of resources, opportunities, and time are most frequently identified blocks to creativity. This is why some organizations are more deliberate about supporting creativity through specific units

designated for creative activity and research and development. Creativity labs, business incubators, makerspace, innovation garages are some examples of such places.

Entrepreneurship is another solution to the creativity gap. Entrepreneurs are the ones who identify potential ideas to grow, invest in those ideas, and turn them into something profitable and beneficial. They literally “buy low and sell high” as was described in Sternberg and Lubart’s Investment Theory. As more entrepreneurs try out new ideas and possibilities, more of the creative potential is put to practice and experimented. Creativity gap, that is fundamentally about unfulfilled creative potential, is thus closed.

Conclusion

Creativity gap has been defined and used in different ways in the literature. However, these conceptualizations share one thing in common, which is the amount of unfulfilled potential to create. Creativity gap is higher when one does not live up to his or her creative potential. Creativity gap indicates how much a person is away from actualizing oneself. This gap may show itself in certain time periods, on a specific region, or under certain contexts such as informal settings. What amazes most people about creativity is its representation as a final product, which may take the form of a groundbreaking artwork or innovation that changes the way we live and perceive the world. What should be frightening to an educator or leader is the creative potential that was ignored, unnoticed, unrecognized, or untapped. A primary purpose of education and leadership at any level should be to reduce this creativity gap.

Creativity Models in Contemporary Psychology

History is contemporary in the sense that it is out of history that any contemporary society grows. Although history seems like a fact-based and past-oriented field, it is also always discussed in the present with an implicit view to the future. History must be ecologically distilled to be ingested, hence someone has to select which qualitatively or quantitatively impactful events are part of it (Carr, 1961). Consequently, the interpretation of historical events can and does change based on context. For example, Columbus day (i.e., a national holiday to celebrate Christopher Columbus's arrival in the New World, Americas), while celebrated by some, can be insulting for certain groups of people (e.g., native Americans).

Similarly, creativity models can be curated in numerous ways based on the aspect of creativity a scholar focuses on (e.g., levels of creativity, domains of creativity, creativity components, and relationships between individuals and environment). In this entry, creativity models are chronologically introduced since 1950, which is time when explicit, empirical creativity research began, at least conventionally. In 1950, less than 2 in 1000 of the listings in *Psychological Abstracts* were related to creativity, and this rate increased to about 10 in 1000 by 1980 (Amabile, 1982). Although the roots of creativity conceptions can be different depending on culture (Niu and Sternberg, 2006), the relatively parsimonious definition of creativity used in scientific research is based on producing something new and task-appropriate (Hennessey and Amabile, 2010; Kaufman, 2016). This operational definition is also shared in studies from many cultures.

Unfortunately, not all creativity models are included in this entry. However, the authors acknowledge that they are part of the incremental development of the field of creativity. Possibly, knowledge about world history and events may be helpful for finding patterns when reading the creativity models discussed below.

The 1950s

In the 1950s, the cognitive processing framework had a great influence in creativity research. Before this information-processing perspective, Wallas (1926) had already developed his individual creative stage model, consisting of five steps: preparation, incubation, intuition, illumination, and verification. Guilford's (1950, 1967) Structure of Intellect (SI) model was conceived to be an approach to intelligence, but his model had a significant impact on creativity due to its proposal of divergent thinking and convergent thinking. These two types of cognition became the foundations of the most routinely used creative test: The Torrance Tests of Creative Thinking (Torrance, 1971) which was utilized, for instance, in approximately 15.3% of the US elementary gifted education programs (Callahan et al., 2013).

Alongside the individual mental processes of creativity, group creativity was also an area of interest. Alex Osborn's (1957) Group Creativity is based on the assumption that creativity in a group can be fostered through strategies such as brainstorming. Despite his argument of the effectiveness of brainstorming and its popularity, other research does not support it (Diehl and Stroebe, 1991). Especially when an employees' cognitive style is systematic (e.g., logical rather intuitive), a brainstorming-like unstructured approach decreases rather than increase creative idea generation (Sagiv et al., 2010).

Another concept present in early models of creativity is that of creative domains. Snow (1959) conceptualized two dichotomous domains, art vs. science. Architects were often studied in this context since architecture is believed to require both artistic and scientific creativity (Hall and Mackinnon, 1969; Mackinnon, 1962). A related distinction is represented by Cropley and Cropley's (2009) functional and aesthetic creativity. Furthermore, creators in the arts and sciences can display somewhat different personality traits; artists are more likely to be emotionally unstable and disagreeable than scientists (Feist, 1998). Extraversion, as an independent factor, significantly predicted creative achievement only in the arts (Kaufman et al., 2016). Even within the two-broad themes, there are some personality differences within domains. For example, performing-art students were more extraverted than visual-art

students (Silvia et al., 2008); creative scientists are more extraverted and less disagreeable than less-creative scientists (Feist, 1998). The Kaufman Domains Of Creativity Scale (Kaufman, 2012) is a more recent example of adopting the artistic and scientific domains of creativity model and extending them to more areas: Scholarly, Self/Everyday, and Performance. Domains of creativity will be revisited and discussed later in this entry.

The 1960s

Rhodes (1961) organized the creativity studies up to that time into four major categories: person, process, product, and press (environment). This model is called the Four P's and has influenced how creativity researchers conceptualize the phenomenon and the kind of questions they systematically ask: What are creative people's characteristics? How do people successfully create? What are the criteria for creativity? How does environment affect creativity? Later, Runco (2003) and Simonton (1990) respectively argued that adding *potential* and successful *persuasion* is important for creativity research beyond the Four P's Model. Although *potential* and *persuasion* can be part of creative *people* and the creative *process*, respectively, they both can be independently significant since *potential* values intrapersonal creativity and *persuasion* values sociocultural interactions with others in the creative process.

Campbell's (1960) Blind Variation and Selective Retention (BVSR) tried to explain the individual creative thinking process, embracing individual differences. It is different from pure cognitive problem-solving perspectives (e.g., the mechanical trial and error problem-solving mechanism) in that BVSR embraced insight, the powerful influence of the environment on creative thought processes, and drew inspiration from biological theory (i.e., Darwin's natural selection). Simonton (2010), recently argued that BVSR could explain many dimensions of genius-level creativity after comprehensively reviewing Campbell's theory. Although it is controversial whether the variation is blind or random (Kronfeldner, 2010), evolutionary variation-selection perspectives are still useful to understand creativity in contemporary neuroscience (Dietrich, 2019).

Mednick's Associate Theory (1962) has a different root than Guilford's idea generation and evaluation although his Associate Theory explains an individual thought-process similar to Guilford's. Mednick emphasized the cognitive ability to connect remote concepts to generate original ideas. For example, the word, "fish" may commonly help British people come up with the word "chips." More unusual answers, such as "sauce" and "church" would be considered as more creative or indicating of creative potential. However, using the same example, many Vietnamese would associate it with "sauce" since fish sauce is a critical ingredient. Also, pious Christians could easily connect it with "church" due to the historical symbol. This example demonstrates the impact of individuals' background factors (e.g., language skills, knowledge, and culture) on their association ability, as a creative thinking construct. Consequently (and also for other reasons), measures of the remote association theory do not have a robust validity when it comes to creativity (Shen et al., 2016).

Whereas most cognitive psychologists were emphasizing individual creative processes, Cummings (1965) focused on the press/environment of creativity. Trying to explain a creative organization's processes, Cummings and O'Connell (1978) developed their Systematic Model of Organizational Innovation by analyzing the characteristics of creative organizations from a systems view. They suggested the five stages of innovation processes: "(1) search for the source of the problem, (2) alternative generation, (3) alternative evaluation, (4) selection and initiation of an alternative, and (5) acceptance and routinization" (p. 33). Also, they categorized the two major forces to initiate the process of innovation: gaps between goals and performance, and monitoring behavior for opportunities from the environment.

The 1970s to 1990s

Kirton (1976) placed creative people on the spectrum from *Adaptors* to *Innovators*. To conceptualize creative people, his framework takes into account interactions between organizational context and individual traits. *Adaptors*, for example, display behavioral characteristics of conformity, collaboration, discipline, efficiency, prudence, and stability; on the other hand, *Innovators* are more likely to challenge existing rules, take control in an unstructured situation, act insensitively to others, and generate shocking and seemingly impractical ideas. Interestingly, he found that more females were closer to the *Adaptors* type than males, and later another researcher also supported this gender difference (Foxall, 1992). This gender difference was also found in the educational setting. Male students' creativity was more accurately assessed by teachers who see creativity as innovative; female students' creativity was more accurately assessed by teachers who see creativity as adaptive (Gralewski and Karwowski, 2018).

Gruber's (1988) Evolving Systems Approach focused on developmental and incremental characteristics of the creative process, with the underlying logic that even Big-C innovators repeated the same creative task for improvement throughout their life. So, a creative process would be similar to a personal constructive learning experience. However, his model also emphasized the dynamics of a creative individual's social network (e.g., collaboration, available knowledge, and chance) as well as the creator's purpose, curiosity, emotion, and insight. Thus, from Gruber's perspective, Van Gogh's work can be interpreted as a combination of the artist's deliberate practice, passion, meaning, and planned behavior rather than an inspirational moment arising from his purported madness (Brower, 2003).

Csikszentmihalyi's Systems Model (1988) explicitly chose three factors to answer the question, "Where is creativity?" He thought that creativity occurs as a result of dynamic interactions among *field* ("a set of social institutions"), *domain* (a stable context that preserves and selects ideas), and *individual* (an agent). He pointed to the Renaissance as a time when a community's wealth

supported talented artists to be innovative. This Systems Model, although decades old, is flexible enough that it can explain current fast-changing technology and communication domains, such as YouTube (Henriksen and Hoelting, 2016).

Amabile (1982, 1983) and Amabile and Pratt (2016) suggested a componential theory of creativity. This sociocultural framework and its measuring method, the consensual assessment technique, are based on intertwined components of creativity at both the individual and organizational levels: domain-relevant skills, creative-processing skills, and intrinsic motivation. In individual/group creativity, domain-relevant skills include knowledge, technical skills, and specific talents, and creative-processing skills contain risk-taking attitudes and ambiguity tolerance. Her conception of intrinsic motivation is a core fuel of creative behavior. Unlike extrinsic motivation (e.g., incentive, grades, and reputation), people with high intrinsic motivation can be driven by internal reasons, such as fun, pleasure, satisfaction, and a sense of connection to the world or others (Ryan and Deci, 2000). This internal force for creativity was also elaborated by the concept of Flow referring to the states of transformative joy without awareness of oneself and external situations (Csikszentmihalyi, 1990). On the other hand, organizational innovation consists of interrelated components of management skills, resources, and motivation to innovate (Amabile and Pratt, 2016).

John-Steiner (1992) argued that the creativity research in the 50s, 60s, and 70s was mostly about creative individuals removed from social context. She supported the importance of social interactions in creativity, influenced by the Russian theorist Vygotsky, whose writings had been recently discovered by the West. Vygotsky's sociocultural learning theory viewed learning as a dynamic result from internal cognitive processes and interpersonal interactions (e.g., mentorship and apprenticeship) in a culture and language where an individual's cognition is situated (McCormick and Scherer, 2018). In particular, John-Steiner focused on the creative process arising from the tension between independent personal growth and growth dependent on others, such as disciplinary-interdisciplinary and expert-novice relationships.

The Investment Theory of Creativity (Sternberg and Lubart, 1991) borrowed a metaphor of the financial market ("Buy low and sell high") to explain creative people's "defying the crowd" attitudes and characteristics. The theory argued for six different constructs that need to align for such creativity to occur: intrinsic motivation, optimal levels of intelligence and domain-knowledge, an open personality, a self-directed thinking style, and opportunities from a creativity-nurturing environment. In their model, creative people can see undervalued ideas, and they are capable of persuading the market to appreciate the ideas. Creators then "sell" the ideas at a high price before pursuing new ideas. This view can explain the relativistic nature of one of the pillars of creativity construct, originality. As soon as a majority of people agree that an idea is creative, the idea may lose its newness. For example, Monet's painting technique would not be considered as original and creative now since his impressionism is not new anymore. Recently, Sternberg's (2018) Triangular Theory of Creativity (defying the crowd, oneself, and Zeitgeist) expanded the Investment Model.

Woodman et al. (1993) developed a Multilevel Model of Organizational Creativity that focused on interactions among characteristics of a person, a group (as a mediator between an individual and an organization) and an organization. These three creative units are seen as mutually influencing creative behavior and the creative environment for successful organizational creativity.

The Propulsion Model of Creativity (Sternberg, 1999; Sternberg et al., 2004) explains different impact levels of creative contributions in a field. Its authors suggested a taxonomy with eight categories: 1) Replication, 2) Redefinition, 3) Forward incrementation, 4) Advance forward incrementation, 5) Redirection, 6) Reconstruction/redirection, 7) Reinitiation, and 8) Integration. The first four types of creative contribution sustain and move forward a field, whereas the last four take the field in new directions.

The following uses the field of jazz as an example, jazz musicians who cover a song and try to sound like the original artist contribute to sustaining the domain (Replication). Improvisation is a core distinguishable factor of jazz. Louis Armstrong redefined improvising as an independent status beyond the traditional composition and performance of music (Redefinition). Swing jazz was a modern evolution from more original style jazz due in part to its danceable quality (Forward incrementation). This type of creative contributions is most common. Miles Davis embraced electronic instruments and non-jazz components regardless of controversy, influencing future jazz generations (Advance forward incrementation). Cool jazz deliberates soothing and comfortable sentiment beyond fast Bebop and danceable Swing (Redirection); Funk re-focused on popular and danceable beats rather than mellow or dizzy melodies (Reconstruction); Bebop was separated from Swing, gaining an independent power as an art from itself apart from Swing's entertaining danceable component (Reinitiation); Bossa nova is a result of samba and jazz, but jazz itself is a synthesis of African music and European instruments/format (Integration).

The Geneplore (Generate-Explore) model (Finke et al., 1992) is consistent with Guilford's cognitive framework due to similarities between the two broad creative cognition stages (idea generation and evaluation). However, the Geneplore model is more elaborate with details of mental visualization skills, imagination, and applications in different types of creative expressions (e.g., creative inventions and concepts). It consists of five sub-steps: Generative Process, Preinventive Structure, Preinventive Properties, Exploratory Processes, and Product Constraints.

The 2000s

Unsworth's (2001) Matrix Model is more focused on industrial and organizational productive creativity. The model is divided into four categories of creativity based on two central questions about interactions between individuals and organizations: "What makes people engage in creative and innovative activities?" and "What initiates people's creativity?" The first question can be answered with the help of a motivational continuum (external vs. internal) and the second question with a problem-type continuum (closed vs. open). Open problems include proactive problem-searching. Closed problems, however, are already perceived, shared, and

presented in a group. Thus, *Responsive* creativity (external $\times$ closed) refers to solving a specifically given problem for an external reward. *Expected* creativity (external $\times$ open) includes a problem-discovery process for external reasons. *Contributory* creativity (internal $\times$ closed) is voluntary creativity on a specific problem. *Proactive* creativity (internal $\times$ open) includes intrinsically motivated creative actions on a discovered problem.

Piirto's Pyramid model (1995) includes many possible factors of talent development for gifted education. Later, she developed the Seven I's model that explains the seven different creative processes: Inspiration, Imagery, Imagination, Intuition, Insight, Incubation, and Improvisation (2004). In general educational settings, Treffinger et al. (2002) developed the COCO model that includes four *interdependent* constructs: Characteristics (person), Operations (process), Context (press), and Outcomes (product). They also developed a systematic assessment tool for classroom teachers to foster their students' creativity based on the students' creativity developmental stages: not yet evident, emerging, expressing, and excelling.

Florida's idea of the Creative Class (2012, 2014) goes beyond the scope of individual or organizational psychology. He argues that a community is similar to an agent that acts in a constantly changing dynamics. Creative communities (or groups) have common tendencies: high-levels of technology, tolerance to differences, and many talented people. Aspects from this community view can be translated into respective evidence-supported creative factors from individuals: *technology* into resource affordances (Karwowski and Lebuda, 2013), *tolerance* into the openness aspect of personality (Kaufman et al., 2016), and *talented* people into both cognitive ability (Plucker and Esping, 2015) and domain knowledge (Batey et al., 2010).

The Amusement Park Theoretical (APT) model (Baer and Kaufman, 2005) aimed to explain the nature of both domain-specific and domain-general creativity. This metaphoric model is hierarchical including (1) general initial requirements (e.g., intelligence or motivation—an equivalent to an admission ticket and transportation), (2) thematic areas (e.g., the arts or science—such as a zoo and cartoon character park), (3) domains (e.g., journalism in writing—a specific cartoon character park, such as Disneyland), and (4) micro-domains (e.g., newspaper journalism—a specific attraction or ride).

Galenson's *experimental creators* and *conceptual creators* (2005) are two different types of creativity that are both valuable in society. Experimental creators tend to evolutionarily create based on the trial and error principle. Conceptual creators tend to more discreetly create things beyond the current paradigm. For example, Cézanne's work was a result of his perfecting and experimental processes, but Picasso started with the breakthrough conceptual idea, Cubism. These two types of creativity can be seen as comparable to the concepts of Kirton's (1976) Adaptor vs. Innovator model as discussed above, continuous and discontinuous creativity in Goswami's (1988) quantum theory perspective, and Gilson and Madjar's (2011) Incremental and Radical creativity within an organization.

The Four C's Model proposes a developmental trajectory of an individual's creative development. An expansion of traditional concepts of little-c (i.e., everyday creativity) and Big-C (i.e., genius creativity) concepts (first articulated by Csikszentmihalyi, 1988), Beghetto and Kaufman (2007) first added *mini-c*, creativity that is personally meaningful and new (e.g., self-awareness). Subsequently, Kaufman and Beghetto (2009) added another creative level, *Pro-c*, expert-level creativity, between little-c and Big-C. Pro-c occurs when an individual begins to contribute to a field and can extend throughout that creator's life. The transition to Big-C typically happens after a creator's death.

Runco (2007), as an advocate of creative potential, suggested two separate hierarchies for creativity research: *creative potential* and *creative performance*. Creative potential includes Person, Process, and Press, whereas creative performance consists of Products, Persuasion, and interactions between a person and environment.

The 2010s to Current

Contemporary creative models are generally more diverse and complex, taking into consideration the arts, sociohistorical views, groups, benevolent intention, brain, knowledge, emotions, and many other concepts.

Glăveanu views creativity as an inseparable phenomenon from historical and cultural contexts. His creativity paradigms (2010) and A Five A's Model (2013) are grounded in a view of dynamic individual-society interactions. The first model explains modern creativity in different time-periods of paradigms: the He-paradigm (e.g., solitary genius view, especially before the 1950s), the I-paradigm (e.g., cognitive and personality approaches of the 60s and onwards), and the We-paradigm (e.g., creative collaboration and co-creation as emphasized from the 80s onwards).

The Five A's Model is Glăveanu's sociocultural adaptation of the 60's Four P's Model. With this lens, *Person* turns into *Actors*, *Process* into *Actions*, *Product* into *Artifacts*, and *Press* into *Affordances* (material and personal resources) and *Audiences* (both those who offer mentorship and feedback as well as those people who will interact with the final product). All components are seen as interdependent.

The Reciprocal Model (Forgeard and Mecklenburg, 2013) added another dimension of creative force, self-oriented (self-serving)/other-oriented (prosocial) beneficiaries from social perspectives beyond intrinsic and extrinsic motivations. Thus, the four categories emerged based on the two dimensions: *Growth* (intrinsic motivation $\times$ self-oriented benefit), *Gain* (extrinsic motivation $\times$ self-oriented benefit), *Guidance* (intrinsic motivation $\times$ other-oriented benefit), and *Giving* (extrinsic motivation $\times$ other-oriented benefit).

The Motivated Information Processing in Groups Model originated from group decision-making (De Dreu et al., 2008), and was expanded to creativity and innovation (De Dreu et al., 2011). The focus is on the function of group members' levels of prosocial motivation and epistemic motivation in organizational innovation. Epistemic motivation refers to a willingness to deliberately and

thoroughly understand the world beyond apparently given information. Thus, when members show higher prosocial and epistemic motivation, group creativity may be more likely to occur.

Batey's (2012) New Heuristic framework is aimed to holistically measure creativity by integrating current creative assessment models and tools. It has three dimensions: creative levels, facet, and measurement. Creative levels include the four units of creative action: individual, team, the organization, and the culture. The creative facet follows the Four P's Model: personal trait, process, product, and press. Finally, measurement is divided into three categories: objective, self-rating, and other-ratings (e.g., teachers rating their students).

In Tinio's (2013) Mirror Model, a consumer of a creative artwork follows the reverse-process of the artist's creative process. In essence, an artist's completed product is the last stage of the creative process, but the product is the first stage of aesthetic experiences for an audience. This model highlighted the pivotal role of the audience in the interactive process of creativity and aesthetics.

Conclusion

This entry used a chronological approach to show how creativity theories have evolved and developed over time. It is important to note that a single model cannot explain a multi-faceted concept like creativity. It would be similar to how linear historical materialism, proposed by Marx and applied to many European countries, would be of little use in explaining India's history, which is rooted in a non-linear concept of time (Saha, 1990). Comparably, a timeline chronicling the Antiquity-Middle Ages-Renaissance periods, where the role of religious power was vital, would not apply to Korea's last dynasty, which has survived without a national religion for about 500 years. Similarly, China's history could fit in through the framework of a series of dynasties, rather than competing feudal lords, since China was centralized about 2500 years ago. Just as no approach works for all countries, so too is each model limited by its context, approach, and the theorist's perspective.

The word "contemporary" may carry the impression of complexity, or even chaos or cutting-edge, when you think about contemporary arts or music. Similarly, contemporary creative models may seem haphazard without a universal principal or assessment tool. However, this state of affairs can also be considered healthy since knowledge gained from empirical studies can always be replaced by more accurate results, and the mechanisms of the human mind are impossible to summarize in a single model.

Although many contemporary theories try to explain observable creativity, human creativity is not all about scientific or artistic progress based on creative or innovative achievement. Human creativity, we believe, is also pivotal for people to harmoniously get along with nature, others, and ourselves (see Glăveanu and Sierra, 2015).

Finally, human creativity needs to recognize all the different types of being creative specific for a diversity of human beings, such as a 12-year-old Native American girl living in Alaska, a five-year-old Muslim boy in Israel, a Christian family in Syria, and a North Korean defector, and European expatriates living in South East Asia. Thus, the hope for the future is to see more inclusive creative models that honor this diversity and value its implications.

Strategies Actions taken during execution of creative thinking processes.

Training

Creativity, defined as the production of original, high quality, and elegant solutions to novel, complex, and ill-defined, or poorly structured, problems, is the basis for progress in the world. Creative problem-solving underlies the internet, synthetic fabrics, and micro-lending—just to mention a few innovations. The value of these innovations led firms (both for profit and non-profit), the educational system, and societies, in general, to search for the interventions likely to encourage creative problem-solving—interventions such as incentives, work design, and supervisory practices.

One of the most common interventions used to encourage creative problem-solving is education, or training intended to enhance the skills, capacities, or attitudes held to contribute to creative thought. Indeed, recent evidence pointing to declines in children, and young adults', creative thinking abilities has led to a new press for more effective educational programs intended to develop creative thinking skills. Moreover, the value of sustained innovation to firm survival has led many firms to institute creative training programs for occupations such as engineering and marketing.

This entry will examine the nature and the effectiveness of creativity training. The beginning will provide details about the objectives of creativity training programs and the methods used in appraising their effectiveness. Next the content of creativity training programs that have proved especially effective in enhancing creative problem-solving skills will be described. Finally, the generality of these conclusions across institutional settings and populations will be considered.

Objectives

At first glance, it might appear the objectives of creativity training programs are straightforward—to improve creativity. It has long been recognized, however, that creativity is a highly complex phenomenon. Thus, some creativity training programs, such as the instructional program developed by Parnes (1967), seek to develop peoples' ability for divergent thinking or the capacity to generate multiple ideas. Other programs, such as the program developed by Onarheim and Friis-Olivarius (2013), seek to develop peoples' capacities, or underlying capabilities, for solving creative problems or to provide instruction that will improve peoples' attitudes towards, or beliefs about, their competence for creative work—an example may be found in Davis and Bull (1978).

[☆] *Change History:* October 2019. Michael Mumford updated the text throughout the article.

This article is an update of J.J. Caughron, D.R. Peterson, M.D. Mumford, Creativity Training, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 311–317.

Not only do creativity training programs differ with respect to their basic goals, they also differ with respect to their specificity in regard to the creative performance of interest. Some programs, especially educational programs for K through 12 students, seek to improve creative thinking across a wide variety of tasks. Other programs have a narrower focus, seeking to improve creative thinking in a specific task domain. In fact, Baer (2012) argued these more narrowly focused, or domain specific, instructional programs may prove especially effective.

To complicate matters further, the objectives of training vary with respect to the specific cognitive capabilities the program is seeking to develop. Mumford et al. (2012) pointed out that creative thought involves multiple capabilities—problem finding, information gathering, concept selection, conceptual combination, idea generation, idea evaluation, implementation planning, and solution monitoring. An instructional program that seeks to develop problem finding skills has very different objectives, and very different instructional methods, than a program which seeks to improve conceptual combination or focused on idea evaluation.

In addition to goals, domain, and specificity, the objectives of training programs must take into account yet another consideration—exactly who are the people to be trained? The instruction required for eighth graders is clearly quite different than for experienced engineers. Moreover, different target populations (i.e., different groups of people) have different personalities, beliefs, and self-concepts, all of which act to influence how one might go about providing creativity training.

In this regard, one key consideration must be taken into account. The populations to be given creativity training differ markedly in their expertise, or knowledge, with respect to a particular domain of performance. As Scott et al. (2005) showed, the nature of the knowledge that people have, and the way this knowledge is structured or organized (i.e., peoples' mental models), has a significant impact on both how creativity training should be developed and the methods to be used in appraising the effectiveness of this training.

Evaluation

Sometimes training works, and sometimes it does not. Ambiguity with respect to the effectiveness of training points to another key consideration. The effectiveness of creativity training programs must be evaluated—how much change in creativity is observed as a result of instruction? In fact, the measures used to appraise the effectiveness of creativity training should not only be reliable and valid measures, they should be measures tied to the objectives of training. Thus, a program focused on improving idea generation should use a domain appropriate measure of divergent thinking. A program focused on improving creative problem-solving should be evaluated using a measure of performance—for example, judges' appraisals of solution quality and originality on a set of relevant creative problems.

The next issue to arise in evaluating the effectiveness of training pertains to the design used to appraise change as a result of training. Broadly speaking, there are two basic designs that might be employed in appraising change in creativity as a result of training. First, one might compare groups who did, and did not, receive the training. Note, this simple design can be made more complex by using groups who receive placebo training (i.e., training irrelevant to creativity), or different forms of instruction. Second, one can use one group of trainees where the measure(s) of creative outcomes are administered prior to instruction, and, again, after instruction. This pre-post design assesses the effectiveness of instruction by looking at changes in performance on these outcome measures. Again, this simple design may be extended to incorporate considerations such as the development of parallel forms of pre-post measures or appraising the maintenance of training effects over time by administering the outcome measure at varying points in time (e.g., three and six months) following instruction.

In evaluating creativity training programs, as is the case with any other training program, it is generally desirable to consider multiple relevant outcomes. For example, if divergent thinking measures are used, it is desirable to appraise multiple aspects of divergent thinking such as the number of ideas (fluency), the range of ideas (flexibility), and the originality of ideas (novelty). Not only should multiple measures be employed in evaluating the effectiveness of instruction, the transfer of the effects of instruction should also be assessed. For example, does the effects of creativity instruction for engineers' result in more patents, or invention disclosures, when the engineers go back to their jobs?

In addition to examining multiple outcomes and transfer, or generalization, of training effects to real-world settings, another point should be kept in mind when evaluating the effects of instruction. Viable evaluation of creativity training programs requires the use of control measures. For example, a program intended to improve creative problem-solving skills might not have resulted in changes in problem-solving skills per se; instead it might have increased motivation to solve creative problems. Such effects can be ruled out as competing explanations for the effects of instruction, but only if appropriate controls are employed. In some cases, controls may be taken into account through the use of additional measures intended to assess the specific variables of concern. In other cases, additional groups will need to be included in the study designs to allow the unique effects of the instructional intervention to be isolated.

Content

Many creativity training programs have been developed and evaluated using very different methods. For example, Feldhusen (1983), and his colleagues, developed a set of audio-taped lessons for enhancing divergent thinking. These short, fifteen-minute instructional sessions present a key principle for enhancing fluency, flexibility, originality, and elaboration followed by illustrations of this principle. Subsequently, students work through a set of exercises intended to illustrate, and provide practice, in the application of these principles.

Another instructional system was developed by Parnes and Noller (1972). This program focuses on improving key creative problem-solving processes such as problem finding, information finding, idea finding, solution finding, and acceptance finding. Instruction is delivered through a lecture and discussion framework where the nature of this model is described along with its implications for creative work. Subsequently, key processes are described that provide strategies for removing blocks to creativity and techniques for effective process execution. Lecture and discussion on a given topic are followed by exercises intended to illustrate key points and provide practice in applying techniques that improve application of these problem-solving processes.

Another instructional program focused on conceptual combination, a key creative thinking process, was developed by Warren and Davis (1969). In this program, participants were instructed how to analyze key features of a problem. Instruction was then provided as to ways people might combine and reorganize concepts, or features, of the problem (e.g., change shapes, re-arrange parts, add or subtract something). In addition, the use of these techniques in creative problem-solving was demonstrated.

Clearly, these programs differ in key objectives, instructional procedures, level of specificity, and evaluation criteria. In fact, over the years, a variety of different course content has been formulated for creativity training. Recognition of this point led Scott et al. (2004a) to conduct a study intended to identify the different types of content used in creativity training programs.

This study began with a review of the applicable literature to identify all creativity training programs proposed over the years. Ultimately, some one hundred and fifty extant training programs were identified. A panel of three judges, all doctoral students with an interest in creativity training, were asked to review the description of the training programs provided. They were asked to rate each program with respect to creative thinking skills stressed (e.g., problem definition, conceptual combination, idea generation), instructional techniques used (e.g., divergent thinking, convergent thinking, ideation, brainstorming, metaphors), media used in instruction (e.g., lecture, videos, social modeling, cases) and the type of performance exercises used (e.g., classroom exercises, team exercises, domain-based performance exercises, imaginative exercises). Judges showed good agreement in evaluating training courses with respect to these attributes. In addition, judges were asked to evaluate characteristics of the target population (e.g., younger vs. older trainees, gifted vs. not gifted students) and instructional parameters (e.g., course length, amount of practice, depth of instructional manual) to provide a set of external reference measures. The judges' ratings of each course attribute were used to form a profile, or a description, of the course. Subsequently, a cluster analysis was conducted to identify the general types of training used to develop creativity. In addition, these types (i.e., groups of similar courses) were described with respect to target populations and instructional parameters. Each program type was described using mean differences from other courses above, or below, a half a standard deviation.

It was found that eleven different types of courses were used in creativity training: 1) analogy training, 2) open idea production training, 3) interactive idea production training, 4) creative process training, 5) imagery training, 6) computer-based production training, 7) structured idea production training, 8) analytical training, 9) critical/creative thinking training, 10) situated idea production training, and 11) conceptual combination training. Figure one provides a summary description of each type of training on the course description measures and the references measures. (Table 1)

The types most frequently used were found to be situated idea production training, structured idea production training, and imagery training. Other instructional techniques such as critical/creative thinking training and open idea production training were used less frequently. Of course, the frequency with which people used a given type of training approach has little to say about the effectiveness of this training approach. The effectiveness of creativity training was examined in another study by Scott et al. (2004b).

Effective Content

In the second Scott et al. (2004b) study, evaluation data bearing on the effectiveness of these creativity training programs was examined in a meta-analysis. The study examined not only the overall impact of creativity training, but also the key characteristics of courses that resulted in more, or less, effective creativity training. Effectiveness was assessed with respect to the four outcome measures most commonly used in studies of creativity training 1) performance on divergent thinking measures, 2) performance on creative problem-solving tasks, 3) real-world creative performance, and 4) attitudes toward creativity. Cohen's d was used to assess effect size where a d below 0.40 indicates a weak effect, a d between 0.40 and 0.60 indicates a moderate effect, and a d above 0.60 indicates a large effect. Across all outcome measures for all instructional programs the average d obtained was 0.68. The strongest effects were obtained when the outcome measures examined divergent thinking ($d = 0.75$) and creative problem solving ($d = 0.84$). The weakest effects were obtained for real-world performance ($d = 0.35$) and attitudes ($d = 0.24$). Thus, creativity training is, apparently, valuable as a technique for improving creativity. Indeed, this finding has been confirmed in another, independent, study.

The next set of questions examined in this study considered the key attributes of more, or less, successful creativity training courses. Here judges' ratings of course attributes were correlated with obtained effect sizes obtained for the various outcome measures. It was found that training programs stressing problem identification, idea generation, implementation planning, concept selection, and conceptual combination were strongly, positively, related to overall program effectiveness ($r = 0.49$). Moreover, instructional programs stressing these processes resulted in much better creative problem-solving as well as better real-world performance and attitudes toward creativity.

Another key characteristic of effective creativity training programs is that they provide practice, substantial practice, in solving domain-relevant creative problems. The effect sizes obtained in creativity training programs were found to be strongly, positively,

related to providing realistic practice exercises, providing more practice time, having depth in practice material, presenting different material, and giving viable feedback with respect to viable performance models. Thus, effective creativity training programs apparently provide substantial domain-relevant practice in executing key creative thinking processes. As might be expected, effective creativity training programs are likely to employ both individual and group performance exercises, often using case-based and cooperative learning techniques, along with modeling and viable coaching as people work through relevant practice exercises.

When providing feedback, however, some instructional techniques appear more effective than others. Encouraging convergent thinking and critical thinking, along with constraint analysis, was strongly, positively, related to the effect sizes obtained in creativity training programs. In other words, instruction that gets people to focus on providing viable solutions, and constrained solutions, to the problems at hand is beneficial. In contrast, more open instruction, and instruction encouraging the use of imagery, metaphors, and self-expression, typically undermined the effectiveness of creativity training. Indeed, these findings were consistent with earlier findings indicating that imagery based instructional programs, despite their wide-spread use, are the least effective way to provide creativity training.

Strategy Training

Scott et al.'s (2004a, 2004b) findings point to a straight-forward conclusion: effective creativity training seeks to develop requisite creative thinking processes through extensive domain-specific practice. This observation, however, broaches another question. How should one go about encouraging effective execution of requisite creative thinking processes? One answer is to provide people with more effective strategies for working through, or executing, each process.

A series of studies by Mumford and his colleagues (e.g., Mumford et al., 2012) began to identify the key strategies people need to use in executing the various processes contributing to creative thought. For example, in problem definition, people should define problems with respect to procedures and constraints, not goals. In information gathering, people should search for key facts and anomalies bearing on these facts. In concept, or case selection, they should search for a diverse set of concepts, or multiple cases, that might allow them to organize facts vis-à-vis anomalies. In conceptual combination, they should search for shared features of relevant concepts and elaborate extensively on emergent new features. When generating ideas, they should extensively explore potential applications of these new features taking into account constraints, whereas, in idea evaluation, they should seek to compensate for potential deficiencies in ideas prior to selecting workable ideas. In implementation planning, they should forecast extensively taking into account both constraints and resources, while, in adaptive monitoring, they should identify key diagnostics constantly seeking feedback on performance.

The value of training in these strategies was demonstrated in a study by Scott et al. (2005). In this study, participants were asked to assume the role of a principal of a new experimental secondary school and formulate a plan for leading this school. Judges appraised plans for quality and originality. Prior to starting work on this problem, participants were presented with a number of relevant concepts and given instruction to search for shared features of these concepts and elaborate on the implications of the shared features that were identified. This instruction resulted in creative problem solutions of higher quality and originality.

In another study along these lines, Osburn and Mumford (2006) asked participants to formulate a plan for leading an experimental secondary school where judges were asked to appraise the quality and originality of curriculum plans. Prior to starting work on these plans, participants completed a set of self-paced instructional modules focused on strategies that might contribute to effective implementation planning such as identification of key causes, actions under personal control, interdependencies in actions, and identification of downstream consequences. In training people to use each strategy the strategy was defined, its application in creative problem-solving was illustrated, practice in using the strategy was provided on a set of semi-structured problems, and practice was provided on more open-ended problems. Findings indicated that people who received this strategy training produced more creative problem solutions than those who did not receive this training.

Clearly, instruction in strategies contributing to effective execution of various creative thinking processes does seem to contribute to viable creativity training. In this regard, however, it should be noted that while some strategies are specific to a certain process, other strategies appear to contribute to effective execution of multiple processes. Mumford et al. (2012) argued that forecasting, casual analysis, and constraint analysis all might contribute to effective execution of multiple creative thinking processes. In keeping with this observation McIntosh et al. (2020) found that more extensive forecasting contributes to both better idea evaluation and better idea generation.

What should be recognized here, however, is that instruction in viable cross-process strategies also appears to contribute to more effective creativity training. Hester et al. (2012) and Marcy and Mumford (2007) provided, or did not provide, participants with strategies for thinking about, or working with, causes in creative problem-solving—for example, thinking about causes that have direct effects, thinking about causes you can control, and thinking about causes that work synergistically. Following training in the Marcy and Mumford (2007) study, participants were asked to solve a series of social innovation problems, while in the Hester et al. (2012) study, they were asked to provide solutions to a creative marketing problem—an advertising campaign for a new high energy root beer. In both studies judges appraised the quality, originality, and elegance of creative problem solutions. And, in both studies, it was found that providing training in causal analysis strategies contributed to the production of more original, higher quality, and more elegant solutions. Other studies have provided evidence for the value of training cross-process strategies bearing on constraint analysis and error analysis.

Taken as a whole, these studies indicate that training people in thinking strategies, both process specific and cross-process strategies, contributes to effective creativity training. In this regard, however, three key considerations should be taken into account when developing such programs. First, strategy training is unlikely to have much value if people lack the basic expertise needed to work through creative problems arising in a given domain. Secondly, some creative thinking processes are more important to performance in some domains than others—thus, in the social sciences conceptual combination is especially important whereas in health sciences problem definition is more important. Accordingly, instruction is most likely to prove effective if it focuses on strategies used in executing critical creative thinking processes. Scott et al. (2005) showed different strategies are used in creative thinking when different types of knowledge (e.g., case-based or conceptual) are employed. Thus, strategy training should take into account the types of knowledge and level of expertise in the population to be trained.

Conclusions

The foregoing observations are noteworthy because they imply the development of effective creativity training programs will require a careful, and thorough, analysis of the type of creative problems people are presented with a domain, the processes critical to solving these problems, and the strategies that allow people to execute these processes. Assuming one has done their “homework” in this regard, and participants have the requisite domain expertise, then it appears that training will have real value as a vehicle for enhancing creative problem-solving.

In fact, the evidence examined in the present effort indicates that if such training provides people with the strategies needed to execute key creative thinking processes and provides extensive practice in applying these processes, and strategies, in solving domain-relevant problems, training may prove to be a potentially powerful technique for enhancing creative performance. Of course, this observation implies creativity training must be disciplined, and focused on performance within a domain, if it is to prove effective. Although such disciplined and focused training may take time to develop, the time required to develop viable training programs, however, does seem easily justified given the strong effects viable training programs have been found to have on divergent thinking, creative problem-solving, creative performance, and attitudes toward creativity.

Introduction

The criterion problem is the challenge of identifying who is creative and what aspect of a product identifies it as being creative (Shapiro, 1970). The criterion problem has lasted over seven decades and is still one of the most challenging issues in creativity research. The criterion of creativity is defined as what should be considered to determine the creativity of a person or product. Although the criterion is often led by people's insight, it should be established on rational grounds. What determines the rational grounds of creativity relies on thoroughly analyzing the characteristics of creative products and their intrinsic nature. However, it seems that there is little agreement on the rational grounds of creativity, which yields conflicts in defining what the criterion of creativity should be.

The following questions may elicit where the conflicts in the criterion problem specifically come from: What is the ultimate criterion of creativity? How are substitute criteria defined in relation to the ultimate criterion? Is creativity tangible and observable regarding outcomes such as products and persuasion? Or is it in the potential such as processes, personality, and places (i.e., environment facilitating people to be creative)? When determining creative products, can quantity of performance serve as a predictive proxy of its quality? Is self-perception of individuals' creativity equivalent to individuals' creativity recognized by their products or other people?

There is no single correct answer to these questions. Reviewing what has been studied to answer these questions may show why determining the criteria of creativity is still challenging. Thus, this chapter shows that the criteria of creativity range widely by which level of creativity is considered, whether to use quantity of performance as a predictive proxy of quality, and even who might be adequate judges of creativity. Also, challenges attributed to the criterion problem are discussed.

Ultimate Versus Substitute Criteria

Delineating the rational grounds of creativity is the key to identifying the ultimate criterion of creativity. Regarding the intrinsic nature of creative products, Ghiselin (1963) summarized four requirements for the essence of ultimate criteria, although a few more characteristics may need to be added. First, the products must be physical or spiritual things created by the agency of human which is distinct from the products of mere existence or natural production (p. 31). Human production assumes purposeful creation by humans excluding the accidental consequences of human's acts. Take an ax, for instance, as illustrated by Ghiselin (p. 35), a product constituting of stone and stick is counted as creative only when humans intended to put them together in order to embody the designs (i.e., meaning or concepts) of the mind.

Next, the products should be "intrinsically a configuration of the mind, a presentation of constellated meaning, which at the time of its appearance in the mind was new and unique (Ghiselin, 1963, p. 36)." Because the individual components of the products may have been used widely or are familiar to people, the simple aggregation of the individual components does not create any meaning. Simply speaking, the whole is greater than the sum of its parts as the unique associations among the parts make the products creative.

More importantly, the associations (i.e., products) should be created for the first time in their history, affirming their origination. The ax creator related stone to stick to embody his or her idea in a meaningful way that no one has tried before, indicating that his or her idea is the origin of an ax. Of course, the original production can be later repeated or slightly modified, but it should be merely considered reproduction.

However, some modifications may change the meaning of the products. This is illustrated in the example of the B. F. Goodrich Company slicing surgical tubing into rubber bands to be sold (Ghiselin, 1963, p. 37). If the modification produces meanings distinct from the preceding ones, it goes beyond mere reproduction and can be regarded as creative. One of the key differences between reproduction and creative products is that the modification contributes to a spiritual addition. In other words, the creative

products should add unique meanings beyond what exists by restructuring preceding ones or extending their applications. Nevertheless, Ghiselin clearly differentiated the level of creativity between initiating its creation and extending/advancing its applications; the former is defined as higher creativity, and the latter is defined as lower creativity.

The rational grounds described by Ghiselin theoretically justify what should be considered for the ultimate criterion. It is ideal to find and evaluate the ultimate criterion (the product meeting the four requirements) to assess creativity. Yet, we need to leverage the level of the criterion to obtain practicability of its use. In the mid-1950s, a group of psychologists including J. P. Guilford, Frank Barron, Benjamin Bloom, and Calvin Taylor, got together for the first time to discuss the identification of creative scientific talent. In the Criterion Committee Report from this conference, [Harmon \(1956\)](#) suggested a measure of the individuals' total creative accomplishment in their entire life as an example of the ultimate criterion. As an example of scientific creativity, several things should be carefully considered to avoid possible errors in approximating creativity of all the products that a scientist created ([Harmon, 1956](#), p. 251). The scientist of interest should be 60+ years old so that the criterion can cover his life span. All his creative accomplishments should be collected throughout his entire life. Objective evaluation tools (or systems) should be set up to rate the creativity of his accomplishments. Then, a panel of scientists should be recruited and asked to judge the creative merit of his accomplishments using the objective evaluation tools. Unless a panel of judges is involved in the evaluation, painstaking historiometric assessment (analyzing a retrospective report of historic figures' creative accomplishment or productivity throughout their life span using objective rules) may be another option as [Simonton \(1990\)](#) has used in his research on geniuses and historic creators. As seen in the example, assessing the ultimate criterion takes enormous cost and time which is not quite feasible with most products of creativity.

This challenge encourages the development of substitute criteria which are more feasible and practical. The *intermediate criterion* is what can be measured at the earlier stage of an individual's life and is expected to be highly correlated with the ultimate criterion ([Harmon, 1956](#), p. 252). For instance, the intermediate criterion could be evaluating individual early-career scientists' creative accomplishments collected until their early 30s such as papers, patents, and membership/officership in scientific organizations, participation in creative activities, or amount of training required for the accomplishments. Instruments, such as [Holland and Nichols's \(1964\)](#) Extracurricular Achievement Scale and [Hocevar's \(1979\)](#) Creative Behavior Inventory in various domains, measure intermediate products.

Still, the intermediate criterion might not be the most cost-effective way of evaluating creativity. To this end, sample behaviors demonstrating the typical mode of functioning as a scientist may be counted as approximate criteria, assuming that those behaviors are highly correlated with the ultimate criterion. For instance, a person is given a problem to solve, which is an essential task for being a scientist, then judged on how he or she solves it ([Harmon, 1956](#), p.254). In the divergent-thinking tests, creative problem-solving tests, and tasks of formulating scientific hypothesis, products serve as *immediate criteria*.

Thus, depending on the level of the criterion, products can be immediate, intermediate, or ultimate creative products. The criterion problem still remains, in part because there is a need to decide which level can be used for the criterion. Additionally, depending on which time period is used, the criterion may change.

Product Versus Potential as the Criterion

Tangible and observable products are usually favored in defining creativity over creative potential which is yet to be covered. [Plucker et al. \(2004\)](#) reviewed 90 articles in major creativity journals and synthesized common themes emerging across the articles in defining creativity. They proposed that "creativity is the interaction among aptitude, process, and environment by which an individual or group produces a perceptible product that is both novel and useful as defined within a social context (p. 90)."

Key attributes of a perceptible product are observability and tangibility of produced outcomes. They suggested that observable and measurable evidence promotes scientific investigations of creativity. Products are criteria that are easily quantified and objective which provides the quantified reliable scores. It is fairly easy and straightforward to say people who won awards such as the Nobel Prize, the Academy Awards, or Golden Globe Awards are creative because of the face validity of those awards as discussed by Simonton in the Awards entry in this Encyclopedia. However, the perceptible products may not be necessary. As noted in the rational grounds of creative products ([Ghiselin, 1963](#)), the products are the material objects embodied by a group of thoughts (e.g., meaning, insights, ideas, images, esthetic realizations). In this sense, the real products of the mind are the subjective realizations of the thoughts themselves, not the objects, as they are merely assembled outcomes ([Ghiselin, 1963](#), p. 33). According to this notion, the thoughts themselves can be considered the criterion; they have yet to be embodied.

One of the probable reasons is that creative products may depend on more than just creativity. Although people have creative abilities, they might not be manifested unless they obtain the knowledge and skills necessary to produce creative outcomes and are motivated to do so. In fact, creative innovation can be carried out by experts only through extended deliberate practice. Due to these probable obstacles eliciting creative performance from potential, identifying criteria representing creative potential is worth paying attention to particularly in populations who have not had opportunities for deliberate practice. For instance, non-professionals may not yet be creative because they have not acquired specialized knowledge and skills in a domain. This may be for many reasons including lack of resources, opportunities, time, or motivation. When considering that a great deal of inequity is seen in educational resources and opportunities in children, product-based criteria discourages uncovering creative potential. Thus, the potential-based approach, identifying the criteria related to cognitive process, personality, and places, is still worthy of attention.

Take ideational behaviors as an example, [Runco et al. \(2000–2001\)](#) argued that creative performance including creative accomplishments may not be an appropriate criterion of divergent thinking (DT) tests. DT tests are often used as a tool for assessing the potential of creative thinking. In order to examine the extent to which DT tests actually assess creativity (or more accurately a component of creativity), predictive validity is usually investigated by testing correlations between the DT test scores and creative performance. Documented predictive validity of DT test scores is not as convincing as they would need to be, with correlations ranging from zero through 0.6 when counts of creative achievement are considered as the criteria ([Plucker, 1999](#); [Runco et al., 2010](#)). Thus, [Runco et al. \(2000–2001\)](#) proposed ideational behaviors as the criteria of DT which “describe actual overt behaviors (i.e., actions and activities) that clearly reflect an individual’s use of, appreciation of, and skill with ideas (p. 394).” Because the actual overt behaviors only involve ideation and do not necessarily require consequential products or performance, it is argued that ideational behaviors are the appropriate criteria of divergent thinking because that’s what these tests test—ideation. In addition, ideation is independent from external factors such as educational resources and opportunities.

Besides ideational behaviors, indicators assessing creative potential include dispositional traits, developmental experience, and the cognitive processes underlying ideation or solving problems. The measures of these indicators can also elicit the creative potential of people who have yet to fully develop it into a tangible product.

Quantity Versus Quality as the Criterion

One of the most tenable measures assessing individuals’ creativity is the Creative Activity and Accomplishment Checklist (CAAC; [Holland and Nichols, 1964](#); [Hocevar, 1979](#)) which has been widely used in empirical studies (see [Paek & Runco, 2017](#)). All activities and accomplishments listed in this measure are equally weighted and aggregated into a single index which is purported to represent an individual’s creativity in the product-based approach. The more one has experienced creative activities and acquired creative accomplishments, the higher the CAAC scores. Someone may question whether an activity and an accomplishment can be equally treated. Unless quantity and quality are regarded as equal criteria of creativity, they might need to be weighted differently.

Empirical investigations uncovered that some people might be overlooked when either quantity or quality criteria are solely used in identifying their creativity. [Paek and Runco \(2017\)](#) adapted the CAAC to children and computed two creativity scores for each child. One score represents the quantity criterion computed by counting the frequency of ordinarily creative activities. The other scores represent the quality criterion computed by counting the frequency of extraordinarily creative activities and accomplishments. Then, they identified children as highly and moderately creative using the threshold of the top 10% and 25% in each of the quantity and quality scores. Interestingly, they found that children who were identified as creative using the quantity criterion did not fully match those who were identified as creative using the quality criterion. The two criteria agree in only approximately half (33%–50%) of children. The overlap ranged from 54% through 67% among children identified as moderately creative. Given that top 10% is often used as the threshold to determine who is eligible for gifted programs in K-12 schools across many states, it is very likely that approximately half of bright students may not be identified as creative as they actually are which, in turn, inhibits them from receiving educational opportunities that they deserve.

Although this empirical finding implies that the quality criterion is noticeably distinctive from the quantity criterion, there is another perspective which may support the use of the quantity criterion as a predictive proxy of the quality criterion. The order effect is the well-known notion where the more ideas that are generated, the more likely the later ideas are original ([Mednick, 1962](#)). If people generate more ideas, they are likely to produce mundane ideas at the beginning and consequently come up with more original ideas later. Put differently, quantity scores representing the most responses may predict to what extent the responses are original as a whole. This link between quantity and quality in ideation is also empirically supported by high correlations between fluency and originality in DT tests. From this perspective, the quantity criterion can be used as a substitute for the quality criterion although they are not conceptually equivalent.

Self-evaluations Versus Objective Measures

People’s creativity can be assessed in several ways: a) Experts of the domain are invited and asked to evaluate the products that people have created, which is referred to as the consensual assessment technique. The products can be drawings, poems, stories, musical pieces, or performances such as dances and public speech. Because experts judge originality of the products, the consensual assessment technique is regarded as fairly objective. b) Another objective way is to assess their performance. People are, for instance, asked to generate responses to DT tasks, then the generated responses are scored for productivity and originality for each person. c) The third way is simply asking peers or supervisors to rate creativity based on their experiences and observations of people generating creative ideas and solving problems in creative ways.

A great deal of consensus and agreement are found across these objective measures of creativity—expert judgment, performance assessment, or peer and supervisor ratings. Yet, these objective measures aren’t used frequently in laboratory experimental research, or are restricted to research of small samples because they are time and labor intensive. This has led to an increased use of self-evaluation or self-perception of one’s creativity.

However, it is questionable whether self-evaluation is a valid criterion of creativity because of the subjectivity ingrained in self-rating. [Reiter-Palmon et al. \(2012\)](#) summarized two issues regarding the validity of self-evaluations. One is whether people

understand what (personality, attitudes, value, or creativity) they are asked to evaluate. The second is whether people accurately report or assess their creativity (or what is asked to be assessed). These two issues distort the quality of self-evaluations which contributes to their weak associations with objective measures of creativity. In fact, [Reiter-Palmon et al. \(2012\)](#) found that the correlations between self-evaluations and objective measures (i.e., their actual performance in DT tests) are close to zero. Due to the low correlations, someone may question whether self-evaluation really assesses the same construct as evaluated in objective measures.

In contrast, self-evaluations are highly correlated with creative self-efficacy or personality, which is also often measured in self-reporting questionnaires. Thus, it may be fair to say that what is measured in self-evaluation may represent the extent to which individuals are ready to engage in creative work no matter how they actually perform. Because construct validity is not perfectly secured in self-evaluation, the challenges still remain when self-evaluation is taken for the criterion.

Challenges and Future Research Directions

When people ask about what the criterion of creativity is, someone may come up with Leonardo da Vinci while someone else may think of Jackson Pollock who reconstructed Mona Lisa in a modern way. Someone may even think of her classmate who drew a spooky Mona Lisa using jelly belly candies. Because they perceive the criterion of creativity differently from one another, how they operationally define creativity may vary. Operational definitions serve for the basis of assessment tools. A key question in measuring a construct is “does the instrument measure what it is intended to measure?” This is the core of construct validity. Because a criterion is what is purported to be quantified through the measure, validity of the scores quantified by the instrument is threatened when the criterion is not clearly defined as intended. However, it is still challenging to determine what should be selected for a criterion and how to select it.

One challenge is that people often choose the criterion of creativity upon their insight rather than the rational grounds of creative products. If ordinary people, for instance, believe creativity is only represented in eminent work or life-long accomplishments, they tend to believe that creativity may be strongly tied to extraordinary talents rarely seen in a general population including themselves. This belief is not only applied to themselves but also to others around them. They are likely to underestimate people, such as children, who do not have special talents or have yet to manifest their potential. Recall here that there are ultimate, intermediate, or immediate products which can serve for the criterion upon the purpose and context for which creativity scores are to be used, instead of applying their own personal belief of creativity.

Potential is primarily assessed with immediate products. Because products are regarded as more objective and measurable than potential, assessing potential is often questionable despite its significance, particularly in populations who have yet to gain enough opportunities to develop their creativity. Thus, it is important to identify measurable indicators of potential which include dispositional traits, developmental experiences, and thinking processes. Nonetheless, developing potential measures is not easy. For instance, dispositional traits may lower thresholds for certain behaviors. If people are unrestrained by social norms, this trait would make it more likely for them to refuse to endorse what is conventionally asked. Thus, their thought process and behaviors deviate from convention which is more likely to result in new ways of solving problems. Still, nonconformity doesn't guarantee creativity and may lead them to arrogance and hostility toward others.

Diversifying experiences may serve creative development in a similar way as unconventional dispositional traits ([Damian & Simonton, 2015](#)). For instance, some people have various adversities in their life such as family loss, poverty, and the discrimination which is attributed to their status as minority or their harsh backgrounds. Because these experiences are rare and highly unexpected in general populations, they would formulate their perspectives through various unique experiences with high emotional intensity. Because these diversifying experiences equip people with new perspectives which are not restricted to social norms, people with these experiences are likely to turn into eminent creators. Yet, this link is only apparent in artists but not in scientists, implying differences subject to domains. Put differently, the prediction of creative potential, such as dispositional traits and developmental experiences, may vary by contexts and domains which leads us to hesitate regarding potential as the eligible criterion of creativity.

Lastly, because the measurable indicators of creative potential often result in poor or unstable psychometric qualities, creative potential may be argued to be a fluffy construct which makes it questionable as a criterion of creativity. Poor and unstable psychometric qualities are attributed not only to fluffy constructs but also to the way in which the constructs are measured. For instance, self-reporting questionnaires are the most preferred as well as widely used in measuring potential despite the limitations of using self-perception for the criterion of creativity. Still, potential can be measured in many different ways by cutting down subjectivity as well as intensifying the link of potential measures to actual creative performance and accomplishment. Tools measuring potential objectively need to be further developed and validated.

Criticism

Creative problem solutions, the production of original, high quality, and elegant solutions to novel, complex, ill-defined or poorly structured problems, provide the basis for the development of innovative new products or services. When people are presented with novel, complex, ill-defined problems, however, many potential solutions, many ideas for problem-solving, are possible. And, students of creativity have long recognized the fact that people typically generate multiple ideas for solving creative problems. Indeed, this key fact underlies [Guilford's \(1970\)](#), and others', work on divergent thinking.

Ideas for solving creative problems, however, are fuzzy. By the term fuzzy we mean to imply that it is not evident either to the person generating ideas or others appraising these ideas as to how successful any given idea will be in solving the creative problem at hand. This inherent uncertainty is the basis for the old adage – don't criticize creative ideas. And, in fact, many involved in promoting creativity explicitly tell people don't criticize ideas, be open to the possibilities.

By the same token, in creative problem-solving people, in general, and creative people, specifically, due to their divergent thinking capacities, produce far too many ideas to allow viable creative problem solutions to be pursued. As a result, virtually all models of creative thinking hold that following idea generation ideas must be evaluated, and a small number, often a single idea, is selected as a basis for the creative problem-solving effort. The notion that ideas must be evaluated, however, implies criticism of ideas is critical to successful creative problem-solving efforts. Accordingly, in the present effort we will examine how criticism contributes to creative performance. We will begin by considering the importance of idea evaluation in creative thought. Subsequently, we will consider the role of self-criticism and interpersonal criticism in the production of creative problem solutions.

Idea Evaluation

[Mumford et al. \(1991\)](#) proposed the most widely accepted model of creative thinking processes. This model holds that creative problem-solving requires effective execution of eight distinct process: 1) problem definition, 2) information gathering, 3) concept/case selection, 4) conceptual combination, 5) idea generation, 6) idea evaluation, 7) implementation planning, and 8) adaptive monitoring of solution implementation. [Mumford et al. \(2012\)](#) have shown this process model does, in fact, provide a compelling description of the key processes involved in creative thought.

In initial work on the significance of idea evaluation, Runco and his colleagues provided rather compelling evidence for the significance of idea evaluation in creative thought. For example, in one study by [Runco and Vega \(1990\)](#), school children

were asked to complete measures of their divergent thinking ability. Scores on a measure of idea evaluation, assessed by children's ability to appraise idea popularity, were found to be strongly related to their performance on measures of divergent thinking ($r = 0.50$).

Skill in idea evaluation is not simply a prerogative of children. Silvia (2008) presented undergraduate students with four divergent thinking tasks. Participants were asked to appraise which of the ideas they produced were most creative and judges, an external panel, appraised idea creativity. It was found that participants' appraisals of idea creativity closely corresponded to those of external judges – a finding which suggests that people can accurately evaluate the ideas they have produced.

Of course, the key criteria employed in these studies are appraisals of ideas produced as opposed to the generation of creative problem solutions. This issue, however, has been addressed in a study by Lonergan et al. (2004). In this study participants, undergraduates, were presented with either ideas of known high quality or known high originality identified in an earlier study by experts in this work domain. Participants were asked to appraise ideas with respect to operative efficiency or innovation potential, and, subsequently, formulate a marketing plan for the new product under consideration – the 3D holographic television. A panel of judges appraised the quality and originality of these marketing plans or problem solutions.

It was found that the highest quality and most original solutions to this creative problem emerged when high quality ideas were evaluated with respect to innovative standards and when highly original ideas were appraised with respect to operative efficiency standards. Apparently, idea evaluation, and criticism, were employed in a compensatory fashion to improve the viability of ideas selected for problem solving. Thus idea evaluation is an active creative thinking process. Moreover, it appears people can apply a number of different standards in evaluating ideas – standards that lead to acceptance or rejection of ideas and the progressive refinement of these ideas.

These observations, however, bring to fore a new question: what standards do people routinely apply in evaluating creative ideas? Blair and Mumford (2007) presented undergraduates with a large set of ideas that might prove of value to a non-profit foundation concerned with solving social innovation problems. Participants compared pairs of ideas and selected a final set of ideas they believed should be pursued by the foundation. Judges, earlier, however, rated key attributes of these ideas. It was found that people preferred ideas that were easy to understand, provided short term benefits to many, and were consistent with prevailing social norms while they tended to reject risky, time consuming, original ideas. Thus, the standards people apply in idea evaluation often may lead to the rejection of creative ideas.

Licuanan et al. (2007), however, have shown under certain conditions people are more likely to evaluate original, creative, ideas more positively. They asked undergraduates to evaluate the originality of marketing campaigns developed by six teams where the level of idea originality was varied along with the amount of information provided about interactions among team members. Manipulations were induced, or not induced, to encourage deep analysis of idea originality and team interactions. And, original ideas were more likely to be identified by those who thought deeply about ideas and their implications, as well as the interactional processes giving rise to these ideas. Thus evaluation, and acceptance, of ideas required extended deep analysis of the implications of ideas in context.

Self-Criticism

Taken as a whole, it appears people can not only evaluate ideas in idea evaluation, they must also criticize ideas with respect to standards. The question that arises at this juncture, however, is what standards do people employ in evaluating ideas and criticizing ideas with respect to certain standards. In self-criticism, the standards imposed in idea evaluation are selected by the individual working on the creative problem solution while in interpersonal criticism the standards imposed in idea evaluation are selected by others.

In an initial study of self-criticism, Kozbelt (2007) obtained historic commentary Beethoven provided with respect to various compositions. Some seventy explicit self-criticisms of various compositions were found in various letters or conversations. Beethoven's self-criticisms, both positive and negative, were found to be strongly related to 1) listener hours, 2) expert ratings, and 3) number of recordings of a given piece. Moreover, the strength of these relationships increased as Beethoven aged. Thus, it appears professional expertise is one key variable shaping productive self-criticism.

Professional expertise, and the standards for creative performance associated with this expertise, arises from three noteworthy sources. One source is evaluation in the profession. Professional evaluation provides standards for appraising ideas or creative work. Second, interactions with colleagues in accomplishing professional work also provides standards for evaluating creative work. And, in fact, prior studies have indicated creative people working in various fields typically establish contact with other creative professionals, perhaps, in part, to identify and elaborate the standards they apply in evaluation their own work. Third, as people acquire expertise, feedback from experience allows them to establish personal standards for evaluating professional products and ideas.

Although expertise appears critical to effective self-criticism it may not be the only influence on evaluation of the ideas a person has produced. Silvia and Phillips (2004) asked undergraduates to work on the alternative uses tests (e.g., alternative uses for a brick), a common measure of creativity, where judges appraised the creativity of the alternative uses listed. Self-evaluation was manipulated through expectations that participants would or would not be appraised for creativity. In addition, expectations for performance improvement were manipulated. It was found that self-evaluation inhibited effective evaluation but only when people did not

expect to improve over time. This pattern of findings suggests that creative self-efficacy may, along with expertise, contribute to effective self-criticism.

In addition to expertise and creative self-efficacy, however, at least three other variables appear to contribute to effective self-criticism. First, [Strange and Mumford's \(2005\)](#) findings suggest that reflection on past personal experience, self-reflection, may contribute to effective self-criticism. Second, [Medeiros et al. \(2014\)](#) findings suggest that explicit analysis of constraints may contribute to idea evaluation by providing a more elaborate set of standards for evaluating creative ideas. Third, [McIntosh et al. \(2020\)](#) findings indicate that when people look downstream, or forecast, the implications of how an idea might "play out" in the future it may contribute to more effective self-criticism of creative ideas.

Self-criticism does not only occur when one evaluates their already produced ideas, however, but also during the generative activities that lead to the production of those ideas. It is often necessary to refine or alter certain aspects of an idea before its implementation if one is to reach a viable solution, especially in creative scenarios. [Kozbelt \(2006\)](#) asked participants, both art students and non-artist undergraduates, to evaluate each of twenty-two in-progress iterations of Matisse's 1935 *Large Reclining Nude*, one of which being the completed work, in a random order. It was found that quality ratings varied considerably as the painting evolved, although the final painting was still considered to be of the highest quality. Thus it appears that as creators evaluate during generative activities novel ideas may change their perceptions of the problem situation. Although modifications may temporarily increase or decrease the quality of an idea, self-criticism and metacognition contribute to effective generation of creative problem solutions.

In a further study of dynamic evaluation, [Kozbelt and Serafin \(2009\)](#) asked artist and non-artist undergraduates to evaluate the quality of numerous in-progress states of twenty emerging drawings, half of which resulting in highly creative outcomes and half resulting in relatively non-creative outcomes, presented in a random order. They found that trajectories of quality for low-creativity works were consistently incremental and additive while quality trajectories for high-creativity works were more jagged with substantial positive and negative fluctuations over time. A follow-up study by [Serafin et al. \(2011\)](#) asked artist and non-artist undergraduates evaluated the quality of in-progress drawings in a fixed order – the sequential order in which they were originally created. Although they concluded that random presentation is a better methodology for studying subjective assessment of creative output, their results fell largely in line with those of the previous study. This pattern of findings suggests that individuals in creative problem scenarios engage in an interactive hypothesis-testing dynamic, where they may not necessarily predict the outcomes of incremental changes during generative activities, but instead evaluate ideas after their implementation. Thus individuals can take risks that incrementally decrease the quality of a creative work without sacrificing final quality as long as they are able to effectively evaluate the consequences of the modification after it has been made.

Interpersonal Criticism

In an initial study of interpersonal criticism and creativity, [Dailey and Mumford \(2006\)](#) asked undergraduates to assume the role of a member of a review panel appraising proposals that might, or might not, be funded by a foundation. Participants were asked to appraise either three ideas drawn from the educational domain or three ideas drawn from the public policy domain. In their appraisals, they were asked to estimate the resource requirements for pursuing the idea (e.g., time to develop, finances needed) and likely outcomes if the idea was implemented (e.g., positive benefits, organizational disruption). Because all ideas reflected prior real-world cases of innovation, actual resource requirements and outcomes were known. The key outcome measure was how close were participants in estimating actual resource requirements and outcomes when evaluating others' ideas – interpersonal criticism.

Undergraduates of course know more about the educational domain than the public policy domain. Moreover, they were told either the panel's recommendation would be followed in deciding which proposals would be funded (high implementation intentions) or their recommendations were simply informative (low implementation intentions). It was found people's appraisals of others' ideas were quite accurate when they had expertise in the domain and they believed their evaluations would be acted on. Thus expertise and motivation to invest expertise in the evaluation of others' ideas appears critical to effective interpersonal evaluation – not just self-criticism.

The reason expertise and motivation are critical to viable interpersonal criticism has been examined in a study by [Gibson and Mumford \(2013\)](#). In this study undergraduates were asked to assume the role of a marketing manager and provide an advertising campaign for a new product line being fielded by a clothing firm. Final campaigns were appraised by judges for quality, originality, and elegance. Prior to preparing these campaigns, however, participants were presented with a set of candidate ideas by teams reporting to them and asked to provide a written critique of these ideas. Judges coded the criticisms provided with respect to number, amount or length, depth, usefulness, range, complexity, isolation, specificity, risk sensitivity, and operational relevance. In addition, the complexity of candidate ideas was manipulated.

It was found the most creative advertising campaigns were produced by those who provided a limited number of deep criticisms bearing on the ideas presented. Thus, focus and expertise, variables which make it possible for people to boil things down and produce deep criticisms, contribute to viable interpersonal criticism. However, viable interpersonal criticism became more difficult for participants as the complexity of the task increased. Apparently, people need time and space to think deeply about the potential problems in ideas if they are to provide the kind of criticisms that will make a difference in creative efforts.

Social Process

Interpersonal criticism, of course, is common in virtually all real-world creative efforts. Creative people at work have bosses, or leaders, and leaders provide followers with critical feedback on the work they have accomplished – feedback creative people, typically, actively seek out. In the real world much creative work occurs in teams. And, team members typically criticize the work of other team members. Thus, interpersonal criticism seems endemic to real-world creative efforts.

Because interpersonal criticism is a distinctly social phenomenon one would expect that various attributional processes would influence the acceptance of criticism and the adoption and/or refinement of creative ideas. In keeping with this observation, it has been found when the criticism is perceived as legitimate, criticism provided by a leader or an expert, it is more likely to be accepted and more creative problem solutions will emerge. Criticisms are more likely to be accepted, and acted on, when there is a high level of trust between the critic and the person producing the creative idea. In general people are more likely to accept criticism from higher status people – especially when the person is perceived to have expertise and credibility. Finally, criticism is more likely to prove valuable when it is provided under conditions where the target of the criticism has the time and resources needed to think in some depth about the criticisms being leveled at their idea.

Perceived expertise, status, and trust in the critic, along with providing the criticism under appropriate conditions, apparently, influences the impact and value of interpersonal criticism of creative ideas. However, all these variables speak to the conditions under which, or by whom, criticisms should be provided in creative efforts. A key question which remains, however, is what should be the content of the criticisms provided?

Reiter-Palmon et al. (2012) in a review of the impact of team processes on creativity and innovation, came to a straightforward conclusion in this regard. Viable criticisms of creative ideas by others should be based on objective technical considerations not personal criticisms of the person doing the work. Indeed, personalized criticisms may act to undermine a positive creative climate. Farh et al. (2010) findings, in a study of some seventy information technology project teams extends this line of argument. They found that interpersonal criticism was most valuable when it occurred at moderate levels and occurred early on in project work. Thus, even technical criticism, if it is unrelenting and occurs after people have invested much in the creative idea, may prove problematic. As a result, the intensity and timing of interpersonal criticism must be managed if it is to prove of real value in enhancing the success of creative efforts.

Conclusions

The old adage holds don't criticize creative work. In fact, the various studies examined in the present effort lead to a very different conclusion. Criticism is inherent in all creative efforts because the many ideas people produce for solving creative problems must be evaluated – and, evaluation implies criticism. In keeping with this observation both self-criticism and interpersonal criticism have been found to contribute to the success of peoples' creative problem-solving. Moreover, self-criticism during generative activities appears critical to the effective refinement and modification of creative ideas.

Of course, caution must be exercised when criticizing ideas. Personal criticisms, criticisms irrelevant to the technical merits of the idea, have no value. Criticisms should be appropriately timed, and people should think, and think deeply, before they criticize either their own or others' ideas. Perhaps even more critically, those providing the criticisms must know what they are talking about. Viable criticisms appear to be based on real expertise – both self-criticisms and interpersonal criticisms. In fact, given the impact of deep criticisms, based on expertise, on the success of creative efforts, we need to know more about how expertise influences the value and impact of criticisms. We hope the present effort provides an impetus for further work along these lines.

Introduction

Crowdsourcing—a portmanteau of words crowd and outsourcing—refers to outsourcing of a task to a large group of unknown people. Different from a usual outsourcing activity, the task is not assigned to a designated agent but is opened up to an unspecified group of individuals (i.e., the *crowd*) typically via the Internet. Crowdsourcing is increasingly used for wide range of tasks. Some of these tasks do not require creativity at all (such as picture tagging, data entry, text editing, or translation) and use of crowdsourcing in such tasks is often motivated by cost and speed advantages of crowdsourcing over alternative outsourcing opportunities (or over doing a task internally).

What is of interest for this entry is use of crowdsourcing for tasks that require creative thinking. Indeed, crowdsourcing is used for harnessing creativity of the *crowd* for various creative outputs (e.g., ideas, designs, solutions, codes etc.) spanning across different domains within science, arts and business. In science, for example, crowdsourcing contests (also referred to as challenges) helped tackling some vexing innovation problems in disciplines such as physical sciences, chemistry, computer sciences, biology, medicine and many others. The challenges ranged from breakthroughs in the discovery of new drugs to designing algorithms that can transform diagnosis of some diseases. Businesses also often turn to crowdsourcing, for example, by creating online communities for consumers to freely share their ideas for new products (and interact with each other in the process of idea generation) or by organizing design competitions for marketing material such as logo designs or video ads.

The term crowdsourcing was coined relatively recently, in an influential Wired article by Jeff Howe in 2006, and the act of crowdsourcing is often viewed as a new approach. Crowdsourcing, however, has a long history—it has been an effective way to find solutions to some important historical problems and was catalyst for many significant inventions. In the next section, I start with providing a brief history of crowdsourcing creativity, with some illustrative historical examples, to put current crowdsourcing practices in context. I then explain the two main forms of modern crowdsourcing. Next, I discuss why crowdsourcing works for creativity and summarize academic research related to benefits of crowdsourcing. A chapter on crowdsourcing and creativity will not be complete without considering potential downsides of the use of crowdsourcing for creative purposes. I therefore focus on some important challenges entailed in crowdsourcing and discuss ways to address these challenges in the subsequent section. I conclude with a discussion of ethical issues in crowdsourcing creativity.

A Brief History of Crowdsourcing Creativity

The origins of using crowdsourcing for creative outcomes can be traced back to as early as 1714—the Longitude Challenge, or the challenge of being able to determine the position of ships in sea. This was one of the greatest scientific problems in the 18th century; it not only had tremendous economic implications, given the importance of it for a greater control in the world's oceans, but also meant saving thousands of lives. In an attempt to solve this challenge, British Parliament has passed the Longitude Act with £20000 prize (about two million pounds in today's value) for an invention that reliably determines longitude in sea. The expectation of the "Board of Longitude" was that only astronomical methods are likely to address this problem—a view that was also strongly shared by Sir Isaac Newton. To the astonishment of the Board and scientists of London, however, the solution was not based on astronomy and came from an entirely unexpected source. A marine chronometer developed by John Harrison, the son of a carpenter and self-thought clockmaker from Yorkshire, was the best solution to perhaps the most pressing scientific problem of his time.

Britain was not the only country where the creative power of the *crowd* was being leveraged to tackle complex innovation problems in the 18th century. In 1783, then French king Louis XVI offered a generous prize for an innovative method that enables

decomposing sea salt economically. About a decade later, the French Directory, launched a challenge for a breakthrough in the preservation of food, with 12,000-franc prize, which eventually led to discovery of canned food.

The use of crowdsourcing has continued in the next centuries. For example, in 19th century, French Emperor Louis Napoleon III offered a sizable prize for a cheap butter alternative intended for military and lower classes. The winner was French chemist Hippolyte Mège-Mouriès with an invention he called oleomargarine, or the margarine as it is called today.

In more recent history, the *crowd's* creativity led to design of one of the most iconic architectures of the 20th century: Sydney Opera House. The design was generated in response to an international competition for “a National Opera House at Bennelong Point” in 1950's. Danish Architect Jørn Utzon was selected as the winner among 233 entries from 32 different countries.

The examples above are just some of the many important historical innovation problems that have been solved via crowdsourcing. From fire extinguishers to hydraulic commercial turbine, many other inventions have been generated as a response to crowdsourcing.

The golden age of crowdsourcing creativity however coincides with growth of the World Wide Web and especially the Web 2.0 at the turn of the 21st century. Coupled with other advances in information and communication technologies, the creative potential of crowdsourcing has grown remarkably in the digital age. More specifically, these technologies enabled access to knowledge and creative potential of people at a global scale. Some well-known examples illustrating this scale include TopCoder—a crowdsourcing platform for software development with over a million members who have participated some of the thousands of contests—and InnoCentive—a platform in which hundreds of thousands of members from all over the world has achieved an astonishing 85% success rate in solving challenging innovation problems (that come from organizations like NASA, Toyota and many others).

Main Forms of Crowdsourcing Creativity

Crowdsourcing creativity essentially takes two main forms based on whether those platforms rely predominantly on collaboration or competition of the *crowd*.

The first form is *crowdsourcing communities* (also called as collaboration-based crowdsourcing). As the name implies, in this form of crowdsourcing, members of the *crowd* interact and collaborate with each other in the process of generating creative outcomes. The contribution in such communities are often on an ongoing basis (rather than one-off). With regards to the type of activities the *crowd* undertake in the community, there is substantial variance. It ranges from writing novel software codes to the development of new product concepts. What is common across these communities however is that the *crowd* collectively produces creative outcomes.

One example is OpenIDEO platform, developed by the renowned design firm IDEO, where a community of designers tackles complex social problems such as those related to human rights or water sanitation. Another example is open source software (OSS) communities in which voluntary programmers from all over the world contribute new codes for extensions to a software, source code of which is made publicly available (typically via the Internet). Perhaps the most well-known open source project is the Linux operating system, developed by Linus Torvalds a famous champion of free software movement. In a similar vein, some companies (e.g., Dell, Starbucks, Lego) have created their own brand communities for the *crowd* (which consists mainly of their consumers) to share their ideas for new products and services (and other brand-related issues), and comment on each other's ideas.

The second form is *crowdsourcing challenges* (sometimes also referred to as crowdsourcing contests/competitions or tournament-based crowdsourcing). In these challenges, *crowd* members compete with each other to generate the most creative outcome to a problem. The winning outcome is often rewarded with a financial reward that can sometimes be worth millions of dollars depending on the importance or complexity of the problem. Unlike crowdsourcing communities, in which collectivity and collaboration is emphasized, these challenges encourage independent experimentation.

One example is the Crowdspring platform—a global website to run graphic design competitions (e.g., logos, websites, brochures etc.) with over 210,000 members. Another example is XPrize which has launched numerous challenges in wide range of domains including Space, Robotics, Environment and Transportation. Their first \$10 million challenge, Ansari XPRIZE, for example, was for a breakthrough that would make private spaceflight commercially viable; this challenge has led to generation of important discoveries in this domain and has often considered as the main driver of the \$2 billion worth private space industry. Adopting similar structure and principles, NESTA (National Endowment for Science, Technology and the Arts) UK also runs several challenges with substantial prizes. For instance, one of their recent challenges, named after the famous Longitude Prize, offers £10 million prize for solutions that can help overcome antibiotic resistance problem.

It is worth noting that some crowdsourcing platforms may take a hybrid form, i.e., may entail challenges with collaborative elements or the other way around (i.e., may have community with some contests). For example, Climate CoLab platform, found by MIT to address global climate change problem, runs contests while also providing open spaces for interactively developing solutions to problems that *crowd* members deem important. Similarly, some platforms (e.g., InnoCentive) allow/require *crowd* members to form teams with other members; the teams then compete with one another generate to win a challenge.

Benefits of Crowdsourcing Creativity

Crowdsourcing is proving to be an effective tool to harness the collective creativity of people to address wide range of problems, as also illustrated by some of examples provided in the previous sections. The main creative value of crowdsourcing could be

attributed to two unique aspects of it: *scale* and *diversity*. That is, modern crowdsourcing operates at an unprecedented *scale* and involves an unparalleled level of *diversity*, both of which have important implications for creativity.

First, crowdsourcing brings a very large group of people together to channel their energies toward generation of a creative outcome. The crowd could comprise of hundreds, thousands and sometimes hundreds of thousands of people. From a simple probabilistic standpoint, more people means more contributions which in turn means having greater chances of exceptionally creative contributions.

It is therefore not surprising that a substantial portion of prior research has focused on what motivates people to participate to crowdsourcing initiatives. Most of this research has used self-determination theory (SDT) (Ryan and Deci, 2000) as their main theoretical framework to study motivations in this context. In this theory, motivation is considered to have a continuum in which extrinsic motivation (i.e., engaging in an activity for external contingencies) is at one hand and intrinsic motivation (i.e., engaging in an activity for the sake of activity itself) is at the other end. Between these two motivations, various forms of internalized extrinsic motivations (i.e., engaging in an activity to achieve a self-selected and personally valued goal) reside. The distinction between these three types of motivations is based on their relative level of autonomy in self-regulation. Compared to intrinsic motivation, behavior driven by internalized motivations feels less autonomous as it is not naturally driven by the activity itself, but by an external contingency. It is however more autonomous than extrinsic motivation as the process of internalization transforms external contingencies into personally valued reasons for engagement.

Majority of the motivation research on crowdsourcing has focused on a specific context: OSS communities. Specifically, scholars have documented rich evidence regarding the importance of intrinsic and extrinsic motivations as well as several internalized motivations that drive members to contribute their software codes in such communities. These internalized motivations include willingness to improve programming skills, reciprocity expectations, social motivations, altruism or one's own need for the software (von Krogh et al., 2012). Similar types of motivations were identified for various other crowdsourcing communities and challenges. In particular, prior research found that enjoying the creative process, learning, gaining status, social identification, or winning an external outcome such as prizes are the main reasons for crowd's participation (Acar, 2019).

Recent research has also explored how to motivate new *crowd* members to sustain their contributions when their ideas are not chosen for implementation. This makes up a very large part of the *crowd*, given that, by the very nature of crowdsourcing, only a small portion of the contributions could be selected to follow up. For example, in crowdsourcing challenges, typically only one or a few winners are selected out of hundreds of participants. It was shown that, somewhat counterintuitively, actively rejecting new, non-winning *crowd* members is an effective way to strengthen relationships, as this signals that their future contributions are desired, which in turn increases those members' willingness to take part in future crowdsourcing initiatives (Piezunka and Dahlander, 2019).

Researchers have started to go beyond looking at what motivates people to take part in crowdsourcing initiatives, and have addressed how those motivations relate to different outcomes such as crowd's level of effort and activity. For example, Boons et al. (2015) have shown that social motivations (e.g., feelings of pride) are a significant driver of members' activity in a crowdsourcing platform. Arguably a more important understanding the relationship between different types of motivations and creativity. Recent research has taken a step to explore this link: it was shown that (i) motivations have different effects (i.e., positive, non-significant, negative) on appropriateness dimension of creativity, (ii) reward size has different effects on novelty and appropriateness dimensions of creativity (Acar, 2018, 2019).

The second unique aspect of crowdsourcing is its unprecedented diversity. That is, crowdsourcing opens up a task not only to usual suspects (e.g., experts, insiders to a domain) but also to outsiders. The creative value of including outsiders is that they might have novel perspectives (from their own domain) for a problem and that they are not bound by rules and norms within a field or organization, both of which could stimulate generation of creative outcomes. Indeed, empirical research in the context of crowdsourcing (and anecdotal evidence from several breakthroughs in the history of science) has shown that outsiders can outperform insiders in terms of their creativity in solving complex innovation problems (Acar and van den Ende, 2016; Jeppesen and Lakhani, 2010). The results were consistent both for being outsider in terms of technical background (e.g., disciplinary expertise) or social background (e.g., gender).

Challenges With Crowdsourcing Creativity

The scale and diversity that crowdsourcing brings, despite the all the potential benefits for generation of creativity, also brings about some important challenges to harness the creative potential of crowdsourcing. The scale of crowdsourcing sometimes means receiving overwhelming number of contributions from the *crowd*. For example, in a recent crowdsourcing initiative of Netflix (for an algorithm to improve existing Netflix algorithm by at least 10%), almost 45,000 submissions were made and the winning submission had more than 100 individual algorithms. The sheer volume of contributions could make it extremely challenging and resource intensive, if not impossible, to properly evaluate each contribution. That is, recognition of truly creative outputs becomes highly difficult among many other substandard submissions. This issue becomes even more problematic when a large portion of ideas are of questionable quality (which often is the case). Because of, in part, diversity of the *crowd* many contributions are useless for different reasons such as not satisfying challenge requirements, being irrelevant or vague etc.

The case of BP illustrates the paradox of openness, or the double-edged sword of scale and diversity, in crowdsourcing. In April 20, 2010, an explosion in BP's DeepWater Horizon rig caused the largest marine oil spill in history and one of the worst

environmental catastrophes of recent times. Millions of gallons of oil were spilled into Gulf of Mexico. BP turned to crowdsourcing to generate novel approaches to clean up the spill and prevent further environmental impacts in the region. The *crowd* was willing to help; the company received over 120,000 responses from more than 100 countries within just a few weeks. A massive effort was undertaken to sift through these ideas, however a large majority of them were at best of questionable quality. The Guardian newspaper described BP's crowdsourcing endeavor as "a lot of effort for little result".

These paradox of openness in crowdsourcing is arguably the most important conundrum for organizers of crowdsourcing initiatives to navigate. It can have a direct negative of on the value derived from crowdsourcing and discourage use of it altogether. This is because a large number of low-quality contributions generates a significant, but unnecessary resource burden—i.e. evaluation these contributions require substantial effort and time despite being of limited to no value. Moreover, having to deal with an overwhelming number of low-quality contributions could affect how these contributions are handled. Recent research has indeed shown that receiving too many ideas biases idea evaluation in favor of familiar ideas (instead of novel ones) (Piezunka and Dahlander, 2015). In addition, A large *crowd* means increased competition among *crowd* members (especially in crowdsourcing challenges), and therefore might attenuate their expectancy of winning extrinsic rewards. It could in turn reduce creative effort and creativity of *crowd* members (Boudreau et al., 2011).

One solution to deal with overwhelming number of contributions is involving the *crowd* in the evaluation process by, for example, letting them vote on contributions. In its crowdsourcing platform, Lego, for instance, asks the *crowd* to show their support for designs they like and only reviews the designs that achieve a certain level of backing from others. This process, however, may also be prone to bias as illustrated by recent research: crowd members' ratings are often reciprocal in nature (Hofstetter et al., 2018). That is, *crowd* members vote for others to return a favor instead of evaluating a contribution based on its true creativity.

Another potential solution to navigate the openness conundrum in crowdsourcing is focusing only (or at least mainly) on appropriate solutions (Acar, 2019). The reasoning is that appropriateness of contributions is a necessary (but not sufficient) for them to be considered creative; contributions that do not meet the main constraints of a task cannot be one of the most promising creative outputs. Inappropriate contributions therefore, regardless of their novelty, aren't worthy of consideration as they distract attention from contributions that hold greater potential. In sum, having fewer but more appropriate solutions might be a promising way to better leverage the creative value of crowdsourcing. One way to achieve this is designing incentives in crowdsourcing initiatives in a way that promotes participation of people who are more likely to generate appropriate ideas. Prior research has provided some insights in this regard. It was found that extrinsic and intrinsic motivation leads to generation of more appropriate ideas whereas prosocial and learning motivations is associated with lower appropriateness. In light of this, organizers of crowdsourcing initiatives are likely to be better off by encouraging those with high extrinsic motivation and intrinsic motivation while at the same discouraging those with high prosocial and learning motivations.

Scholars have documented evidence for other ways to improve creativity of contributions generated in crowdsourcing initiatives. In addition to the findings related to motivation and creativity discussed before, it was shown that feedback (including negative feedback), task variety and perceived autonomy improve creativity (e.g., Garcia Martinez, 2015; Wooten and Ulrich, 2017). It was also found that experiencing success could be detrimental for subsequent creativity. Studying Dell's IdeaStorm crowdsourcing community, Bayus (2013) has found that members who experience early success with their ideas tend to become less creative because they are inclined to propose very similar ideas to the ideas that brought success to them. He also found that this tendency could be alleviated if successful members diversify their activity in the community by, for example, commenting on other members' ideas.

Ethical Considerations

Crowdsourcing creativity entails several important ethical issues. One important concern is potential exploitation of the *crowd* by not providing fair compensation. Because most crowdsourcing initiatives for creativity typically do not involve any financial rewards or only reward a few select people, most efforts and contributions of the *crowd* are uncompensated. This led some to argue that crowdsourcing creativity is inherently exploitative. Others, however, highlight the wide range of motivations, above and beyond financial rewards, and the voluntary nature of participation in crowdsourcing initiatives. It could also be argued that rewards in crowdsourcing could provide attractive opportunities for people from the developing countries.

Some evidence indicates that *crowd's* perceptions of what makes a fair reward is complex. For example, it was found that not giving any financial reward at all could be better than providing an unfair reward indicating that the *crowd* might have different meanings attached to unpaid and paid crowdsourcing initiatives (e.g., a fun game vs. a badly paying job) (Acar, 2018). In a similar vein, other factors such complexity of a task, or required level of technical expertise or elaboration in that task could also affect perceptions of fairness. This suggests that perceptions about fairness of crowdsourcing is more complex than simply looking at minimum wage calculations—other factors discussed above should also be taken into account.

Another important ethical issue is potential opportunistic behavior (in terms of misappropriation of creative outputs) by the organizers of crowdsourcing initiatives. This issue originates from the paradoxical nature of knowledge disclosure. That is, in order for the value of knowledge (or creative outputs in this case) to be determined, potential acquirer of that knowledge needs to obtain it without any commitments and cost. The knowledge could therefore be potentially misappropriated. Knowledge creators may hesitate disclosing their knowledge due to fear of such opportunistic behavior. Prior research has shown that such fears of opportunism is present among *crowd* members too—even among those who eventually opt for disclosing their knowledge (i.e., active

crowd members) and in well-known and established crowdsourcing platforms (Acar and van den Ende, 2015). An effective way to mitigate such fears is building trust which could, for example, be partly achieved by investing in transparency and communication regarding conditions related to ownership of contributions (e.g., intellectual property rights etc.).

All in all, organizers of crowdsourcing initiatives have moral responsibility to address these issues. This is not only essential from an ethical standpoint but also important for ensuring sustainability of crowdsourcing and deriving better creative value from it.

Conclusion

Crowdsourcing is a promising way to tap into collective creative potential of people. It provides a “playground” for some to hone their creative skills and enjoy their time while also providing many others an outlet to connect with others, contribute to something that matters, and sometimes gain concrete extrinsic financial and non-financial benefits. Despite some important challenges inherent in crowdsourcing creativity, it has proven to be an effective method to tackle various minor and major creative problems at least when designed and managed carefully.

Introduction

The concept of culinary creativity has witnessed a growing public and professional interest over the last two decades, but it is still relatively under-explored academically. The practice of culinary creativity, however, has existed since people were required to be creative in the preparation of their food because of the scarcity of resources or could afford to be more lavish to increase the aesthetic pleasure of their meal creatively. But, it was not before the famous Spanish chef Ferran Adrià published the book 'Los Secretos de El Bulli' ('The Secrets of El Bulli') in 1998 that the concept of culinary creativity piqued public interest. Today almost every TV channel on the planet has a portfolio of more or less 'creative' cooking shows including both laypeople and professional chefs. Before that time, chefs were certainly using their creativity but considered it as a natural part of their artisanal work and craftsmanship without talking about it much.

Academically, culinary creativity is researched through a rather narrow lens that focuses on the upper echelons of gastronomy, called Haute ('high') cuisine, where cooking meets art and sometimes even science. One of the main reasons for this focus on haute cuisine is the institutionalized evaluation of culinary excellence and creative progress through yearly recognition in the leading restaurant guides, the Michelin and Gault Millau. Their publicly available evaluations make it easier for researchers to justify their choice of the sample when studying the creative person, creative process or creative product.

Unquestionably, culinary creativity also exists outside the realm of haute cuisine or the food on the plate and can be found in as diverse culinary fields as fast food, airline food, or home cooking, and regularly ignites inspiration for new gastronomic concept developments, multisensory experience creation or cooking machinery. The latter, developing cooking machinery, is often triggered by the process of finding a creative solution to a particular cooking problem. The famous French chef Michel Troisgros, for example, invented a machine to produce layers of milk skin on a large scale that he requires for his dish 'Raviole de lait caillé,' a ravioli that he makes from milk skin instead of dough. Initially, he started by boiling milk in a pot, like many would do for breakfast at home, and then waited for the milk to cool down to form a skin on top. This technique, though, would have been unusable for the demands of a professional restaurant where chefs need to reproduce a dish several dozen times per service.

More generally, a better understanding of culinary creativity is vital for the advancement of the hospitality and tourism industry that has long been considered a laggard with regards to creativity and innovation and is in urgent need of meaningful rejuvenation. This industry is not only the largest industry in the world, responsible for substantial economic value generation, but it is also one of the last remaining industries that can accommodate low- or semi-skilled workers and thus has a significant social responsibility.

Furthermore, one part of the hospitality and tourism industry, the gastronomic sector, has a rich cultural heritage and forms part of the so-called cultural and creative industries. Ever since culinary creativity escaped from the kitchens of the royal courts, France has contributed, perhaps like no other country in modern times, to the economic and cultural significance of gastronomy. France and its culinary tradition influenced generations of chefs with its sophisticated practices, intricate recipes, and elaborate aesthetics of presenting food. This contribution has recently been recognized by the UNESCO (United Nations Educational, Scientific and Cultural Organization), which declared the gastronomic meal of the French as an 'Intangible Cultural Heritage of Humanity' (<https://ich.unesco.org/en/RL/gastronomic-meal-of-the-french-00437>).

Another reason why researchers predominantly explore culinary creativity in haute cuisine is that culture tends to evolve through the influences of those practicing and shaping practice at the highest levels and who have the power to initiate institutional change. Haute cuisine has witnessed at least two, perhaps three, distinct institutional changes that went far beyond the creation of a new plate of food, involving almost paradigm-like shifts of cuisine styles. All of these changes were rooted in creativity.

Culinary Creativity and Haute Cuisine

The sociological literature has especially looked at the macro-level of culinary creativity by exploring the institutional changes in the field of haute cuisine. In this field, creative work in the professional kitchen was for a long time seen as merely being the refinement of the existing know-how and practices of the French culinary arts. More significant creative leaps in the past were often only recognizable by what could be described as shifts in cuisine paradigms. Similarly to the concept of scientific paradigms, there are paradigms of cuisines that go beyond the individual cuisine of a chef and describe a more aggregate level of cuisine based on agreed beliefs and assumptions that regulate the professional practice. Haute cuisine has witnessed four different types of cuisine paradigms: ancien régime cuisine, classical cuisine, nouvelle cuisine, and avant-garde cuisine. Now and then a new set of beliefs and assumptions develops, and when strong enough challenges the dominant cuisine, trying to initiate an institutional change of the currently dominant cuisine paradigm.

The first such change happened when the so-called ancien régime cuisine paradigm was slowly taken over by the classical cuisine paradigm that was triggered by the French Revolution in 1789. This movement fostered the opening of public restaurants, the codification of professional knowledge, and generally liberated chefs from the very restricted type of gastronomy celebrated in aristocratic or other elite households where chefs were regarded as bondsmen of the ruling classes (Ferguson, 1998; Rao et al., 2003). One of the leading proponents of this movement was the French chef Antonin Carême (1784–1833) who pushed the idea in his writings that haute cuisine is both science and art. He was followed by two other French chefs, Georges Auguste Escoffier (1847–1935) and Prosper Montagné (1865–1948), who, by then, represented a very different breed of chefs, more business-minded and often hired for their abilities to manage large kitchen brigades and create gastronomic identities for entire hotels. Perhaps the most prominent example here is the collaboration between chef Georges Auguste Escoffier and the famous Swiss hotelier César Ritz, who, in his function as manager of the Savoy Hotel London, hired Escoffier to manage the hotel's gastronomic outlets and staff. After years of experience in similar positions, Escoffier published *Le Guide Culinaire* in 1903 that became a standard for generations of chefs to come and is still considered the seminal reference of classical cuisine (Stierand, 2013).

Almost two centuries later, triggered again by major social unrest, the protests in France in May 1968, classical cuisine was subsided by the emergence of nouvelle cuisine that followed a new reflective philosophy of cooking based on truth, lightness, simplicity, and imagination (Rao et al., 2003). Chefs started to use transgression, the use of old cooking techniques in combination with new products, and acclimatization, the adoption of foreign cooking traditions, spices and seasoning, and developed a more self-expressive style of cooking with a greater degree of creativity, more detached from the strict rules of Escoffier's *Guide Culinaire* (Rao et al., 2003). Chefs like Alain Chapel, Michel Guérard, Paul Bocuse, and the Troisgros brothers Pierre and Jean, are notable examples of the nouvelle cuisine movement who expressed more liberal and 'anti-establishment' values in their style of cooking by de-complicating recipes and focusing on the product itself that was used at its seasonal peak and regional availability (Stierand, 2013). The philosophy of nouvelle cuisine made it much easier to apply certain aspects, such as foreign spices and seasoning for home cooking. Even haute cuisine dishes like Heinz Winkler's salmon in puff pastry, found entry to the private home kitchen, because it helped the amateur cook to produce a perfect piece of salmon through protecting it in puff pastry. But, and perhaps most importantly, it inspired many to become more mindful about food, cooking, and eating, giving birth to a number of iconic eateries such as Alice Water's 'Chez Panisse' in Berkeley, California, the fount of the fresh food movement in the US, or Fergus Henderson's 'St-John Restaurant' in London, UK, where he celebrates nose-to-tail eating.

The last significant change to the institutional field of haute cuisine is often wrongly associated with the term 'molecular gastronomy,' which is a branch of food science created by the physical chemist Hervé This and the physicist Nicholas Kurti (Cousins et al., 2010). The media jumped on the term and used it to describe a new style of cuisine that was spearheaded by chefs like Ferran Adrià, Heston Blumenthal and Thomas Keller, but who were, in fact, interested in an artistic style of cuisine based on a better scientific understanding of cooking that could help evoke new culinary experiences. These chefs always favored the term avant-garde cuisine (Stierand, 2013).

Perhaps less known to the public, many insiders consider the self-taught French chef Raymond Blanc, who made his career in the UK, as the godfather of this approach to cooking. He worked with Nicholas Kurti, who became in many ways his mentor, and together they wanted to improve professional cooking scientifically, and sometimes this would also provide possibilities to create new and meaningful culinary inventions. While avant-garde cuisine often appeared very cold and technical at its beginning, it became more and more natural. It eventually led chefs to include foraging, the sourcing of wild foods, in their cooking and the rediscovery of natural preservation methods such as fermenting. Notable examples of this new approach of avant-garde-cuisine are chefs René Redzepi from Denmark and Magnus Nilsson from Sweden.

As said earlier, creativity was a major vehicle for these institutional changes to happen. While classical, nouvelle and avant-garde cuisine represent cuisine paradigms, philosophies of cooking based on socio-cultural and professional assumptions and beliefs, they are often described through iconic dishes that were invented during these times. One of the most famous classical cuisine dishes is certainly Escoffier's 'Peach Melba,' a poached peach with vanilla ice-cream and raspberry sauce that Escoffier invented at the Savoy Hotel London in honor of the Australian soprano singer Nellie Melba. One of the most famous nouvelle cuisine dishes is the Troisgros brother's 'Salmon with Sorrel Sauce.' And the iconic dish of the avant-garde cuisine is certainly Ferran Adrià's 'Melon Caviar.' This dish is made from Cantaloupe melon juice enriched with Algin, a binding agent extracted from brown seaweeds, which is then put in syringes through which the juice is dripped into a calcic bath where the drops form a fragile shell around the juice and turn into caviar-like melon pearls.

Culinary Creativity as a Process

Empirical research on the process of culinary creativity is most often found in the management and organization studies (MOS) literature. Svejenova et al. (2007), conducted a longitudinal inductive study of the critical case of the famous Spanish chef Ferran Adrià to understand how he initiated institutional change through creativity.

Creativity researchers know a good deal about the creative person and the creative outcome, but the process in between that happens upstream in people's minds, often requiring a well-developed level of sensory knowing, is still under-researched from a personality, cognitive, affective and aesthetics perspective. Following the need of better understanding the creative process itself, Horng and Hu (2008) explored to what extent the creative culinary process is comparable to Wallas's classic model of the creative process. A later study (see Horng and Hu, 2009) extended their four-component model to include culinary performance. Then, perhaps providing a more aggregated view of a creative process, Svejenova et al. (2010) built on their previous study of top Spanish chef Ferran Adria and showed how his quest for creative freedom triggered distinct evolutionary phases of his individual business model.

Bouty and Gomez (2013) investigated creativity in three French Michelin-starred restaurants through a practice-based lens and described how chefs engage in three types of creative work, namely individual idea work, creative team work, and naming of the dish. This was followed by a study conducted by Stierand et al. (2014), who showed, based on in-depth interviews with 18 Michelin-starred chefs, that the phenomena of creativity and innovation in haute cuisine did not follow a sequential developmental process based on the principles of operations management. Instead, these phenomena are embedded in a system in which creativity is perceived as an embodied experience that is frequently guided by intuition and in which innovation is mostly the result of the audiences' social evaluation. Stierand and Dörfler (2016) focused on the aspect of intuition and showed how intuitive insight and intuitive judgment are instantaneous yet distinct and rapid processes that seem to be part of the creative culinary process.

The aspect of embodied experience and intuition was looked at in more detail by Stierand (2015) who used a practice-based lens to focus on the situated development of Michelin-starred chefs' high-level creativity, explaining how these chefs went through a master-apprentice relationship. In these master-apprentice relationships, the talented novice chefs developed their own socially appropriate creative voice through intelligent imitation of the master by becoming an improved version of themselves rather than a pale copy of the master. Master-apprentice relationships naturally consist of relational ties that Feuls (2018) explored from the broader perspective of culinary innovation as a relational phenomenon. She was building on Gabriel Tarde's relational sociology and identified three processes of innovating, namely repeating, adapting and differentiating, that chefs seem to follow and that influence the degree of novelty of the creative output (See Mentors).

A rather new but critical perspective for better understanding the process of culinary creativity was then introduced by Bouty et al. (2018: 156). They were interested in how creative teams are led in haute cuisine kitchens and looked through a practice-based lens at their combined research projects on haute cuisine restaurants. They inductively unveiled three dynamics of directing creative leadership practices that they labeled enabling, orientating, and complying.

Discussion and Conclusions

Culinary creativity includes "both the chef's willingness to come up with new concepts and techniques and his ability to do that through methods for creativity and organizing" (Svejenova et al., 2007: 547). Culinary creativity combines food science with art and culture, making it a nonlinear and heterogeneous phenomenon that frequently combines diverse techniques with culinary influences from different historical periods and cultures (Horng and Hu, 2008). More precisely, culinary creativity seems to sit in between the chef's individual culinary style that also includes commercial considerations and a more globally expanding culinary tourism industry with customers demanding an authentically local cuisine cooked to the highest international standards (see Horng and Hu, 2009).

One of the earliest conceptual MOS contributions regarding culinary creativity discussed the link between culinary innovation and the chef's creativity and artistic aspirations that they argued is formed and influenced by the chef's lifeworld (Stierand and Lynch, 2008). Exploring the phenomenology of creativity is important because it can provide a thicker understanding of the micro-practices in and in-between creative work. For example, the studies above on relational ties and the master-apprentice relationship would not have been possible without tapping into the lived experiences and lifeworld of creative chefs.

Through phenomenological and exploratory style research approaches it was possible to find out that chefs who cook a more classical cuisine seem to apply their creativity predominantly to the creation of new dishes, aiming to evoke new emotions through unusual textures or food combinations (Gomez and Bouty, 2009). Avant-garde chefs like Ferran Adrià, in contrast, seem to look more beyond the plate and are fascinated by developing new techniques and concepts, searching for inspiration in other domains and then applying a disciplined trial-and-error process (Svejenova et al., 2010). Moreover, research on the master-apprentice relationship showed that talented master-apprentice chefs typically wander from more classical to the more avant-garde type chef to develop their creativity (Stierand, 2015).

Future research on culinary creativity can and should harvest the low hanging fruits, the big questions that seek answers. One such low hanging fruit is the widening of the research lens to include all levels of the culinary field, at all skill levels, looking at the entire spectrum of the culinary arts, including the person, process, product, and press (See the Four P's of Creativity).

The degree of novelty and nature of appropriateness varies depending on one's creative competence and the perceived or assumed expectations of the audience. It is a different scenario if the audience is family members commenting on a new dish created from the remaining few food items found in the family's fridge or whether professional restaurant critics and food journalists award stars or points for the creations of a professional chef.

Aesthetics also play a role, both as a consideration the creator may use during the creative process but also as a quality the audience may consider for their judgment. It is thus interesting to explore how creativity translates into aesthetic quality and how the aesthetic quality of inspirational stimuli may influence culinary creativity. Just imagine two studies that could potentially offer important contributions for practice and theory. The first study could look into the aesthetic differences between Western and Eastern approaches to culinary creativity, considering both the creator and the audience. The second study could look into the potential aesthetic differences that may arise when the creator is a female or male chef.

One useful lens that researchers could use to explore these topics is the antenarrative lens. In a recent conceptual MOS contribution, Stierand et al. (2019) theorized the process of culinary creativity through an antenarrative lens, arguing that 'having an idea' is a contextualized and embodied process that can be regarded as an antenarrative, a kind of prenarrative thought, of the overall creative process. The benefit of this lens is that it can help to tap into the sociomaterial qualities of the creative process, which can potentially offer deeper insights into the social relationality as well as the playfulness of creative work. Play, it is suggested, seems to be vital for building bridges between the more formative and sudden manifestations of the creative act in the kitchen (See Play).

Research and practice need to join forces in the pursuit of unraveling culinary creativity. World-class practitioners like Chef Ferran Adrià and Chef Massimo Bottura seem to understand this and have initiated important and very interesting projects. Ferran Adrià after having closed his world-famous restaurant El Bulli in Roses, Spain, created the El Bulli Foundation. This foundation is currently involved in three projects. The first is called La Bulli Grafia, which is an archive museum that tells the story of El Bulli Restaurant, a story that resulted from creative auditing. The second project is El Bulli 1846, an exhibition lab that intends to study efficiency in innovation by using the exhibits as research tools. The third and perhaps most exciting project is called Sapiens, which is essentially the method invented by El Bulli Foundation to comprehend and evaluate a project to improve efficiency in innovation. Through this project, Ferran Adrià tries to generalize his method of genius creativity.

Massimo Bottura, chef patron of the famous Osteria Francescana in Modena, Italy, founded Food for Soul. This non-profit organization, in collaboration with a wide range of partners, is dedicated to making people aware of the massive problem of food waste and social isolation and to form and foster community kitchens around the world to recycle food. It is not a charity, but a cultural project that builds these community spaces based on three key principles that they name as quality of ideas, power of beauty, and value of hospitality.

That quality, ideas, and hospitality can bring together people are clear, but what is fascinating to see is that extraordinary practitioners seem to have this deep sensory philosophy, a kind of intuitive wisdom, that tells them that beauty, the stereotypical quality of aesthetics can build bridges between people. The Prince's Foundation has realized the power of beauty too and discovered that when social housing is designed in an aesthetically pleasing way, the buildings require less repair because the tenants seem to take care of them more. What academics can and must learn from these extraordinary practitioners is that they have achieved the top of their game and have shifted the boundaries upwards by allowing not only multi- or interdisciplinary to inform their work but also trans-disciplinarity. That is, they allow the different disciplinary birds to fly freely without a cage.

Cultural Diversity

In 2015 an estimate of 244 million individuals in the world were classified as migrants. This represents 3.3% of all of humanity, and a substantial increase since 1970, when the estimate of migrants stood at 2.3% of the world population. In consequence of such unprecedented levels of international mobility, cultural diversity and multiculturalism have become one of the key challenges of the modern world. Cultural diversity can be defined as the extent of cultural differences that exist between people. Diversity is most commonly discussed in the context of pan-national, national or ethnic groups that are typically characterized by distinct cultural rituals, values, and languages. However, diversity can also be understood more broadly, in terms of differences in religious affiliation, socioeconomic status or in terms of regional differences (e.g., between Northern and Southern regions of a country). This broad understanding of cultural differences is possible with the acknowledgement that “many forms of culture” exist, and that culture constitutes the expression of the values and traditions of a broad range of distinct social groups, including non-national or non-ethnic groups. Drawing on this distinction our article will focus on experiences of cultural diversity understood in a narrower sense (as experiences of multiculturalism, dual identities, or of working in an international environment) but with reference to other, related forms of diversity: e.g., ethnic diversity, demographic diversity, or “deep level”, informational diversity studied in the context of firms and organizations.

The main chunk of this article will consider the influence that diversity has on creative processes. The diversity-creativity link has been examined across many levels of human experience. For instance, while country-level comparisons focused on the disproportionate numbers of first- and second-generation immigrants among Nobel Prize Winners, studies in organizational behaviour attempted to identify which “types” of diversity are most beneficial for divergent thinking, and which ones are most beneficial for idea implementation. In the latter part of the article we’ll discuss issues to do with cross-cultural differences and cross-cultural comparisons, and we’ll consider how varying cultural content (e.g., cultural values) is transferred during cultural exchange. We will also consider the question of cultural fairness and of cultural diversity within creativity research itself, and what consequences these issues may have for cross-cultural comparisons.

Individual Experiences of Cultural Diversity

We begin with a discussion of how individual diversity experiences (i.e., immigration, diversity exposure) link with creative performance and with people’s success at creative achievements. To understand the role that culture and cultural diversity play in individual creativity it’s important to account for both little “c” creativity as well as big “C” Creativity and little “m” multiculturalism as well as big “M” Multiculturalism. Little “c” creativity refers to everyday creative processes and is apparent on testing in the lab or online, using standardized cognitive tasks and psychometric testing tools. Big “C” Creativity refers to the “great person” approach and the achievements of eminent creators and typically relies on archival analyses of great works of art and sciences, and the biographical details of the creators. Due to drastically different methodologies in these two lines of work, the link between “Big C” and “little c” creative outcomes is weakly documented, however reasons exist to believe it exists. Mirroring the “Big C” and “little c” distinction for creativity, a distinction can also be made between long term, immersive experiences of multiculturalism (Big “M”), as well as smaller scale instances of such experiences (little “m”). An integration of both research perspectives is important in order to gain a broader view of the diversity-creativity link. Studies taking the little “m” and little “c” perspective help us understand what processes account for the diversity-creativity link, and can sometimes allow for making causal inferences. Studies of the “Big C” and the “Big M” allow researchers to appreciate how the diversity-creativity link plays out in terms of meaningful creative and innovative outcomes for individuals, groups, as well on a larger, societal scale.

Big “C” Creativity

Several researchers have noted that immigration and biculturalism are linked to a greater success at creative achievements. According to Simonton’s seminal historiometric analyses (Simonton, 1997), throughout Japanese history variation in the degree to which the country was open or not to foreign influences predicted eminent creativity in later generations. Another line of work studied the biographies of 20th century eminent personalities and uncovered that one-fifth of the analysed creators were either first- or second-generation immigrants. In further support of the diversity-creativity link, macroeconomic data from the US over a 10-year period (2000–10) indicated that foreign-born immigrants stimulated economic growth with their disproportionate degrees of eminent creativity and innovation. For instance although foreign-born immigrants represented only 13% of the US population, they accounted for 30% of all the patents granted, and for 25% of all the US Nobel Laureates.

Much theorizing and research has focussed on how the diversity-creativity link driven by immigrants’ individual contributions. For instance Godart et al. (2015) conducted archival analyses of the lives of great fashion designers and uncovered a positive association between these individuals’ multicultural experience, and the creative success of their fashion collections. Godart et al. (2015) distinguished three aspects of multicultural experience: depth (i.e., the extent of immersion in a foreign culture), breadth (i.e., the variety of cultures one was exposed to) and cultural distance (i.e., the extent to which the cultures that one was exposed to were different from one’s original home culture). Their analysis suggested a curvilinear effect in the diversity-creativity link: at lower and moderate levels breadth and cultural distance had a positive link with creativity, however once at a higher level, their link with creativity became null or negative. One explanation of these findings may have to do with saturation effects: perhaps multicultural experiences stimulate creativity at lower levels, but once a sufficient level of stimulation has been achieved, there is no further need for it, leading to a tapering off in the effect. Another reason could be that very high levels of multicultural experience exceed people’s coping ability – too much diversity and multicultural exposure could become overwhelming and threatening to individuals, and this is likely to be exacerbated by a lack of coping resources. In support of the latter idea biographical studies of eminent African-Americans have suggested that minority group membership may enhance creativity, but only in those who remain in good psychological health (Damian and Simonton, 2014).

Little “c” Creativity and Multiple Identities

Cross-sectional research looking at diversity and the “little c” creativity explains what *processes* link multicultural experiences with creative performance. This work theorized that multicultural experiences (e.g., biculturalism, multicultural exposure and cultural diversity) cue people out of schematic thinking patterns, fostering cognitive skills through which multiple perspectives on a problem are acknowledged, learned, and integrated, eventually leading to creative outcomes. Successful acculturation requires that immigrants gain an understanding of and adapt to the values and behaviours prevalent in the host culture. These adaptation processes affect how bi- or multi-cultural identifiers think about the world and their place in it. Membership in one social group or culture allows for smooth operation in line with scripts, norms and values that one has been exposed to in the home and in the family. But as a result of immigration or social mobility, people become members of new groups, which requires them to embrace new cultural values, norms and scripts. Provided that this challenge is successfully addressed, this could lead to the development of more flexible thinking and greater creativity.

Tadmor et al. (2012) conducted a series of studies on how the experiences of bicultural dual identifiers affect these individuals’ performance. In this work dual identifiers, but not immigrants identifying with one culture only, demonstrated higher levels of *integrative complexity*. Integrative complexity entails the ability and willingness to acknowledge and integrate competing perspectives on the same issue. Furthermore, dual group identification was also associated with a greater creativity, innovation in the workplace, and promotion rate at work, and those effects were mediated by increased integrative complexity (Tadmor et al., 2012). Similar observations have been made in bilingualism research. This area may however be problematic, for two reasons. First of all, the robustness of research findings on the cognitive advantages of bilingualism has been called into question in the recent years. Secondly, whether cognitive uplifts observed are due to language developments or second-culture exposure is very hard to establish, as most bicultural individuals tend to be bilingual, and vice-versa. As a result the role of bilingualism in the multiculturalism-creativity link is at present unclear.

Little “c” Creativity and Diversity Exposure

Since the majority of studies described so far have been correlational, it’s hard to judge whether the diversity-creativity link is causal in nature. On the one side it’s possible that multicultural experiences lead to greater creativity, on the other, creative individuals might be predisposed to have more multicultural experiences. Finally, certain personality traits, such as a greater openness to experience, could predispose people to be more creative and simultaneously to be more open to embracing new cultures. The strongest evidence, so far, to a *causal* diversity-creativity link comes from longitudinal research. In a study conducted by Fee et al. (2013) international aid workers from Australia and New Zealand, who were delegated to work in another country, demonstrated an increase in cognitive complexity 12 months following departure (measured against the pre-departure baseline). In a second study cognitive benefits were observed not only relative to ones’ pre-departure score, but also relative to a matched sample of individuals who did not go abroad.

Evidence of a causal link between diversity and creativity can also be inferred from research attempting to simulate the processes that occur during multicultural experiences. For example, [Leung and Chiu \(2010\)](#) invited undergraduates to watch a 45-min-long slideshow that contained various combinations of cultural symbols. After watching images of American and Chinese symbols presented back to back, or pictures representing the American Chinese fusion of cultures (e.g., a rice-burger), participants' responses were more creative, compared with a single-culture (American or Chinese), or a baseline control condition. This "little c" and "little m" research suggests that experiencing a mixing of cultural symbols and norms, which is inherent to the experience of multiculturalism, stimulates greater creativity.

Another line of work focussed on the fact that experiences of multiculturalism and social and cultural diversity challenge people's stereotypic beliefs. In a series of experiments participants were asked to think of counter-stereotypes—targets that violate people's expectations about the traits that they should possess. Thinking of counter-stereotypes led to greater flexibility, the generation of original ideas, and better solutions to insight problems. Notably, the effect was bounded by individual differences in participants' epistemic motivation: exposure to counter-stereotypes lead to greater creativity in people low in the need for structure, however, when need for structure was high, creativity was hampered ([Gocłowska et al., 2014](#)). In a similar vein, research by [Leung and Chiu \(2008\)](#) demonstrated that multicultural experiences increased creativity only when openness to experience was high, but decreased creativity when openness to experience was low ([Leung and Chiu, 2008](#)). Because openness to experience and a (low) need for structure entail people's willingness to engage with things novel and unusual, these traits may regulate the extent to which people are willing to expend resources in the face of cognitively challenging diversity experiences.

Cultural Diversity in Groups

While much psychological research focuses on how social diversity affects individual creativity, a related question is how these processes play out in creative groups and teams. Groups can be diverse in many ways. A corporate team whose members are of different ethnicities, genders or ages is demographically (or "surface") diverse. However, diversity in a group can also be expressed in terms of team members' diverse areas of expertise, their roles in the company, or their different personalities ("deep level" diversity). Furthermore, group and organizational research investigates a very broad range of creativity processes: from idea generation through to innovation processes such as the voicing of or implementation of creative ideas in an organizational setting.

The idea that group-level cultural diversity may enhance creativity can be traced back to Nemeth's work on dissenting opinions ([Nemeth and Kwan, 1987](#)). In a series of studies where a minority of group members (who were really confederates) persistently expressed a dissenting view, the remaining group members were more likely to find innovative solutions, and to generate more original associates. These findings were explained through processes of epistemic motivation: in the presence of dissenting views research participants considered more alternatives and were more open to unusual solutions for fear of coming up with the "wrong" answer ([De Dreu and West, 2001](#)).

Some work supports the idea that these mechanisms can lead to greater creativity in ethnically diverse teams. For instance in the study of [McLeod et al. \(1996\)](#) ethnically diverse (vs. homogenous) groups generated more effective and feasible ideas on a brainstorming task that was relevant to issues of diversity and ethnicity (How to get more tourists to travel to the US?). Another line of work demonstrated that the presence of Black team members in a group task can increase the integrative complexity of essays written by White research participants ([Antonio et al., 2004](#)). Finally, a study by [Vezzali et al. \(2016\)](#) found that when Italian children were asked to work with immigrant children on a cooperative task this led to an increase in individual creativity ([Vezzali et al., 2016](#)).

Notably, the above studies are suggestive of several boundary conditions. Group diversity benefitted creativity on tasks relevant to the topic of diversity, when individuals generated ideas individually (nominal groups), and when differences between group members were deemphasized. Thus, while supportive of the link, these studies revealed that diversity benefits creativity only under a specific set of conditions.

Such a conclusion is further reinforced in management and organizational research. Researchers in these fields argue that out of the various types of organizational diversity, demographic ("surface level") diversity is the *least* likely one to benefit team creativity and innovation. For instance a meta-analysis by [Bell et al. \(2011\)](#) found that while educational, tenure and functional diversity (i.e., differences in experience in various functions in the organization) have a positive relation with team creativity and innovation, gender and ethnic diversity have a small *negative* relationship with team creativity and innovation ([Bell et al., 2011](#)).

Several mechanisms may explain why the diversity-creativity link is rarely observed on the level of group outcomes. First of all, demographic group diversity is most likely to boost performance on a few tasks that benefit from the informational value of this type of diversity. Secondly, effects of group diversity may vary at different stages of the creative process. A third explanation pertains to how ideas from diverse individuals are implemented in team work and team innovation. In spite of their greater levels of integrative complexity or creativity, bicultural or ethnic minority individuals are likely to face barriers during social interaction. Social identity research provides well documented insights on how groups resist influence from minority or non-prototypical group members. As a result diversity is sometimes associated with decreased cooperation, coordination, and cohesion among team members and, ultimately, decreased team performance. Recommendations on how to remedy this do vary, from suggestions that diverse teams should be tasked with idea generation, but not with idea implementation, to calls for the development of more targeted diversity interventions that aim to remove barriers faced by minority individuals.

Cross-Cultural Differences in Creativity

Although much psychological research focuses on ways in which cultural diversity benefits creativity, many have pointed out that creativity research itself is not very diverse. [Leung and Wang \(2015\)](#) have recently analysed creativity-related papers published in top-tier organizational psychology journals (*Journal of Applied Psychology* and the *Academy of Management Journal*) and noted that 70% of papers published there originate from the United States and other Western Countries, with another 20% of samples originating from China. They also noted that most non-Western papers published on the subject of creativity are written from a universalist perspective, not taking into account cross-cultural differences and idiosyncrasies of the culture within which the research had been conducted. This is problematic because of the risk that psychological theories won't be applicable across cultural contexts. Furthermore, vital insights and observations based on non-WEIRD samples (non-Western, Educated, Industrialized, Rich and Democratic) may never be popularized, because they have a relatively low chance of being published in mainstream psychology journals. To address these issues creativity researchers need to consider whether psychological theories that they use are broad enough, whether their participant samples are sufficiently diverse, and whether the psychological tests that they use are culturally fair. This call is also echoed in [Glăveanu's \(2010\)](#) work on the cultural psychology of creativity. [Glăveanu \(2010\)](#) expanded the definition of creativity to "a complex socio-cultural-psychological process that, by working with 'culturally-impregnated' materials within an intersubjective space, leads to the generation of artifacts that are evaluated as new and significant by one or more persons or communities at a given time" (p. 87). Thus, the cultural psychology of creativity suggests that people from different groups might understand creativity differently, and that such cross-cultural differences in the definition of creativity ought to be studied more broadly.

The meaning of creativity differs across national boundaries, with non-Western countries holding a more utilitarian view of creativity and a weaker "art-bias", relative to Western societies. For instance, [Adair and Xiong \(2018\)](#) have demonstrated that Chinese students living in Canada have a more utilitarian view of creativity than Caucasian Canadians, while [Yue et al.'s \(2011\)](#) research showed that Chinese students have more appreciation for the creativity of great inventors or politicians, while German students tend to consider artists and philosophers as highly creative. Further, [Loewenstein and Mueller \(2016\)](#) found that Chinese but not US-American participants judged utilitarian descriptions of products such as "easy to use", "feasible", and "for a mass market" as indicators of creativity. Similarly, [Hanel et al. \(2018\)](#) recently found that Brazilian participants judged professions with a more utilitarian focus such as builder or physician as more creative than British participants.

These findings may be traced back to differences in collectivism and individualism between Western and non-Western countries. Individualism can be understood as an emphasis on the self as independent and agentic, whereas collectivism as an emphasis on a group and one's willingness to sacrifice for it ([Hofstede, 1980](#)). A focus on novelty production is more prevalent in individualist countries such as the US, while a focus on the utilitarian function of creativity is more prevalent in collectivist countries like China (for a more comprehensive review of these differences see [Leung and Wang, 2015](#)).

The individualism-collectivism distinction carries with it not only difference in how creativity is defined, but also differences in performance scores on creativity measures. A host of studies suggest that research participants from Western countries score higher on measures of creativity, compared to research participants from Eastern countries. However, one should also note that other studies show evidence in the contrary direction, both in terms of creative performance as well as differences in lay conceptions of creativity.

Thus, while some studies show that Western students score higher than Asian students on various creative tests, this difference is unstable, and several explanations and caveats should be considered when reviewing these research findings. First of all, the measurement of creativity has predominantly been developed in the USA and according to Western conceptualizations of creativity, and so results of many studies may be biased to capture the view of creativity prevalent on one culture rather than the other. Secondly, discussing collectivism and individualism as an East-West distinction ignores differences that exist between Western countries (e.g., USA vs. Bulgaria), between Eastern countries (e.g., China vs. South Korea), and variability within countries, which, for some variables, such as values, are usually eight to twenty times larger than between-country variability. Third, levels of collectivism and individualism tend to vary across generations as well as social classes, with non-middle class samples responding in more collectivist ways. And finally, the statistical methods used by psychological researchers have been criticised for overemphasizing differences between cultures and countries, and deemphasizing their commonalities.

Summary

In sum, cultural diversity is an important topic of high relevance to the psychology of creativity. Researchers across a range of fields ask about the influence that cultural diversity has on creative performance and innovation potential. Historiometric and experimental work supports the idea that, under the right set of circumstances, individual experiences of diversity can increase people's creative potential. Studies on creativity and innovation in organizational settings are less clear cut, painting a more complex picture and suggesting that although diversity can help groups to generate new ideas, it may also hinder other processes necessary for those ideas to be implemented. Finally, cultural diversity is an important creativity meta-subject, as more needs to be done to make the psychology of creativity diverse, but also to better understand what, in people's conception of creativity and in creative performance, is shared and what is different between cultures.

Dance and Creativity

Dance is a complex and diverse art form. The focus of this chapter is directed towards creativity that is expressed through movement. Ultimately, dance is a form of embodied cognition, including aesthetic and neuroaesthetic embodied perceptions. A brief discussion explores the benefits of dance throughout the lifespan as well as the very real hazards of a typical professional dance career. Whether participating in dance or observing it as an audience member, kinesthetic experiences are shared amongst dancers and their audience. This experience is examined at the physiologic, neurobiological, and perceptual levels in this chapter.

Dance is the oldest form of human artistic expression (Sachs, 1937/1965). In the Hindu religion this is powerfully illustrated; Lord Shiva created heaven and earth while performing the Dance of Creation. All the essential elements of physical existence are evident in dance (Sachs, 1937/1965). It exists simultaneously within time and space, and it always involves the physical body. Even in computer-generated dance, some embodied form or shape is required. In order to be considered a dance, and not just a sequence of movements, intentionality must co-exist with aesthetic appeal (Press and Warburton, 2007). Rhythmic movement patterns and three-dimensional design patterns are physically revealed through the dancer's body. Spatial intention and design elements coexist in the physicalization of dance. These primary factors are the bedrock of dance and they are the key factors identified when assessing creativity in dance (Press and Warburton, 2007).

Throughout the ages dance has appealed to diverse populations. Every individual has an opportunity to dance, whether as an amateur social dancer or a highly trained professional dancer. Today social media incorporates dance as a vehicle to market merchandise, influence fashion trends, or celebrate family or community events. Dance can be witnessed in all settings (i.e., in the end zone when professional football players spontaneously perform a victory dance, in print or media advertising, or in video games). Audience participation estimates are gathered by the National Endowment for the Arts (NEA), however they only estimate attendance at concert dance (excluding commercial dance, social dance, street dance, etc.). According to the 2017 NEA report, 22.8 million adults attended a dance performance. This figure was significantly lower than the 2012 census, where 36.9 million adult American audience members attended a dance performance in a public concert hall. The decrease in adult participation was directly related to a weakened economy. According to the 2017 survey a weakened economy meant that dancers and choreographers continued to produce new works despite reduced paid employment opportunities. They created dances at the same rate without remuneration and with fewer paying audience members.

Dance and Aesthetics

The term, aesthetics, captures the sensual delight experienced by a viewer of a work of art (Calvo-Merino et al., 2008). Aesthetic appreciation is usually informed by a subjective notion of beauty (Kirsch et al., 2016). This appreciation crosses all cultures and all age groups, and includes a vast array of dance styles and traditions (Calvo-Merino et al., 2008). Regardless if dance is presented in spiritual, social, or performance settings, the aesthetic appeal resides in its dynamic movement quality. It is identified in the temporal and spatial movement patterns of dancers, as well as in the human body, the movements that are generated by the body, and the emotional intention behind the movement and body posturing. Dancers and their audience recognize and share this aesthetic experience.

The field of neuroaesthetics is now moving beyond the visual arts and music and is including dance. Like the other art forms viewers of dance employ complex visual, auditory, and reward neural networks. In addition the perceptual and motor networks are integrated into the aesthetic experience (Kirsch et al., 2016). Specifically, viewers who ranked specific dance movements as aesthetically appealing, engaged bilateral visual and sensorimotor regions of their brains (Calvo-Merino et al., 2008). This response intensified when viewers were familiar with dance or had expertise in dance (Kirsch et al., 2016).

Dance and Embodied Motor Creativity

Creativity involves the convergence of cognition and emotion. These two major mental processes influence the creation of the product and how it is received (Gu et al., 2018). In dance the sensorimotor system is also deeply integrated in the aesthetic experience. Trained dancers readily recognize and appreciate the aesthetic appeal of dance vocabulary. They have an embodied kinesthetic understanding of dance and respond to dance performances more intensely than novices (Kirsch et al., 2016). The positive reward of witnessing or executing dance movements is heightened in trained performers. Likewise trained dancers perceive non-verbal motor actions as a form of cognitive verbal language. While creating or performing they continually and simultaneously engage declarative (verbal) and procedural (non-verbal) memories; in fact dance is often processed as a declarative language (Blasing et al., 2009). Ultimately these cognitive, emotional, and memory systems are part of what could be termed motor “cognition” or embodied cognition. Talented dancers excel in embodied cognition and motor creativity. The complexity of these interactive systems enhances a sense of self and others, increases cross-modal self-recognition, and intensifies embodied integration of linguistic meaning and communication (Jackson and Decety, 2004). Along with these heightened abilities dancers who possess increased motor expertise also demonstrate an increased sensitivity to the affective body movements of others. Their heightened proprioceptive and physiologic awareness of others strengthens their social cognition (Christensen et al., 2016).

Despite the reality that expertise in dance enhances aesthetic appreciation all living species can recognize movement, including its purpose to communicate. Neurobiological networks are entrained to respond and implicitly understand movement communication. Our brains recognize the actions of others and can direct appropriate sensorimotor responses in return (Jackson and Decety, 2004); this is the bedrock of dynamic embodied cognition and it extends to embodied abstract thought such as truth, value, and aesthetics. This is why dance functions as a universal symbolic language; it can express abstract ideas and truths, whether at the most remote abstract level of spatial and temporal design or at the more immediate emotionally expressive or narrative level (Kozioł et al., 2012).

These fundamental concepts underpin the emerging research field of embodied cognition; this field of study regards cognition, even abstract thought, as embodied. Embodied cognition implies a biological memory system that encodes information about internal and external physical competencies, perceptual contexts, and motor responses (Gu et al., 2018). Often embodied cognition operates pre-reflectively; instinctive or intuitive responses are mobilized with incredible precision and accuracy. Interactive multi-modal sensory-motor and emotional processes shape the formation of embodied cognition. It is constructed via the specific body we possess, the physical training we experience, and by the particular context within which embodied cognition is grounded (Borghi and Cimatti, 2010). Individual embodied knowledge enhances understanding about other peoples’ movement and intention and it enhances perceptual understanding about the emotional states operating in others (Jackson and Decety, 2004).

Because dance is inherently an embodied art form audiences are readily able to appreciate dance. They have an innate ability to perceive movement and sense another’s movement as if it occurred within their own body. This is even more intensely experienced when audiences view strong dancers who are able to execute powerful coordinated movement that is layered with expressive intent. The audience responds with visceral focused attention, which includes a heightened awareness of physical sounds that operate outside the musical accompaniment (i.e., sounds of breath and body contact with the floor or other dancers) (Reason et al., 2016). Audience members from all cultures respond to dance; our neurobiological systems allow us to recognize and understand movement as well as the emotional and aesthetic appeal inherent in dance (Calvo-Merino et al., 2008).

Dance Education Across the Lifespan

Dance education, whether formal or informal often begins in early childhood and persists into senior years. In academic settings children, adolescents, and college students are given opportunities to freely explore movement with the intention of creating a dance composition (Hagood and Kahlich, 2007; Press and Warburton, 2007). Compositional principles such as form and content, spatial

and temporal intention, and movement phrases and themes are introduced at all educational levels (Hagood and Kahlich, 2007). Students learn to improvise in order to discover movements that express a specific intention. They are able to reflect on the movement material that is generated, examine how groups are organized to enhance aesthetic appeal and emotional intent, and identify and recognize when a composition is successful or insufficient. This ability to examine choreographic elements and manipulate them to enhance creative expressivity is generally promoted in dance education. Although some students also receive formal technical dance training (i.e., ballet, modern, contemporary, jazz, tap, hip hop), the majority of students engage in dance education courses in order to explore everyday movement and to construct movement compositions that express personal experiences (Press and Warburton, 2007). Like the students, dance educators rely on what they describe as “sensing,” “knowing,” “thinking body-mind,” or “whole self-awareness.” They employ embodied intuition and visceral “knowing” to determine whether the quality of a dance performance or performer is good or poor (Chappell, 2007).

While investigating movement novice and experienced dancers discover that assuming specific body postures facilitates the retrieval of autobiographical memories. Assuming body positions that contain autobiographical memories may intensify the emotional expression of the dance (Dijkstra et al., 2007). Likewise assuming body postures and movement sequences might enhance memory retrieval of previously learned dance repertory (Press and Warburton, 2007). These sensorimotor memory systems are integral to the structured “thinking” that operates during professional dance rehearsals and performances. Over time dancers develop an embodied knowing, a way of perceiving oneself from the inside out. They are aware of feelings, movement, and intentions that inform aesthetic decision-making and guide aesthetic appraisal. This form of embodied knowing has also been described as “felt knowing”; for dancers the body and the mind are indivisible (Chappell, 2007).

In the elderly recent research has demonstrated that engaging in the practice of dance enhances sensory, motor, and cognitive functioning. These positive results are directly associated with the demand to coordinate motor movement, while adhering to rhythmic musical patterns, maintaining spatial orientation and awareness, and dancing with a partner in a group (Coubard et al., 2011). Compared to dance, doing simple fitness exercise has far less benefits for the elderly population. Notably, participating in dance enhances cognitive flexibility and quality of life in the elderly (Coubard et al., 2011). Regardless of age long-term participation in dance enhances sensorimotor functioning, including enhanced connections within the cortico-basal ganglia networks. This provides greater coordination and functional integration (Kozioł et al., 2012). In addition, acquiring some form of dance training at any age promotes heightened sensorimotor and affective experiences while performing or observing dance. An embodied understanding of the aesthetic experience of dance is nurtured (Kirsch et al., 2016).

The Dancer: Career Challenges

Given the reality that the aesthetic quality of dance is deeply intertwined with embodiment, dancers frequently experience body objectification. This is a process that diminishes embodied ownership. Objectification intensifies stereotypes of a dancer’s body, especially the image of thinness. Most dancers and their audiences accept these stereotypes, which increases risk for eating disorders and overtraining (Scoffier-Meriaux, Falzon, Lewton-Brain, Filaire, and d’Arripe-Longueville, 2015). As well, many dancers are perfectionistic. They strive to embody aesthetic ideals and perform with an intensity that often increases risk of injury. Professional dancers experience higher rates of injury than most athletes, with prevalence of injuries ranging from 50% to 97% (Air, 2013). The physical demands of dance also limit career longevity, thus dancers often confront an early career transition. Their creative desire to perform is curtailed. This transition from dance is often extremely challenging. Dancers compared to other artists are more emotional, anxious, obsessive, cautious, and less hardy; although they are also intelligent, cognitively and emotionally flexible, and they demonstrate strong achievement motivation (Marchant-Haycox and Wilson, 1992). Despite multiple challenges dancers value the creative process and embrace opportunities to perform and/or choreograph (Press and Warburton, 2007).

Conclusion

Although dance can exist without music, it is generally integrally related to music. The immediacy of dance makes it a powerful medium; it can unite performers and their audience through an interpersonal connection that is facilitated by activation in multiple neural networks, especially the sensorimotor, action observation, and reward networks. Audiences who observe dance readily experience its aesthetic nature, especially when movement is regarded as both pleasing and difficult (Christensen et al., 2016; Kozioł et al., 2012). Even those with minimal exposure to dance can derive a deeper understanding of social cognition; they have an innate ability to understand the language of movement and the emotional content embedded in movement.

Dance is an art form that has existed since the beginning of time. Regardless of changes historically and culturally, dance prevails. Humans are endowed with the ability to appreciate and be aesthetically moved by dance (Calvo-Merino et al., 2008). Embodied cognition resides at the heart of perceptual awareness and motor communication. Embodied motor creativity drives the formation of new dance works; dancers become experts integrating complex mental imagery to motor patterns in order to enhance aesthetic appeal. Dance is an embodied language capable of expressing the most abstract truths and the most profound emotional experiences. Dance is the mother of all the arts (Sachs, 1937/1965).

Discovery of the Default Network

One of the major developments in the field of cognitive neuroscience was the discovery of the brain's default network (DN). Like many well-known discoveries throughout history, the DN was discovered by accident. Around the turn of the twentieth century, neuroscientists began to notice a mysterious pattern of activity in brain scans, mostly obtained through positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). These scans showed consistent activation within a set of regions located along the midline of the brain (medial prefrontal cortex and posterior cingulate cortex) as well as bilateral inferior parietal regions (angular gyrus) that emerged when people were simply relaxing in the brain scanner. One of the neuroscientists that documented this curious pattern of activity was Marcus Raichle and his team at Washington University in Saint Louis, including Randy Buckner. At the time, Raichle and many other researchers had been conducting cognitive neuroscience experiments by comparing some "active" task state of interest (e.g., solving math problems) to a "passive" resting-state where no task was administered. This "rest" condition was thought to be an appropriate control condition to compare to the "active" task condition and was largely considered to be a source of random noise in the fMRI signal. The term "default" network (or default mode network) was coined because it was thought to reflect the brain's default metabolic state when not engaged with the external world (Buckner et al., 2008).

Nancy Andreasen—another neuroscientist (and noted creativity researcher) studying the DN at the time—was among the first to suggest that default activity did not reflect a passive and uninteresting state, but rather a highly active state of internal mentation. Andreasen even devised a clever acronym for this state of "REST" (i.e., Random Episodic Silent Thought). Several earlier observations by neuroscientists provided clues about the existence of an intrinsic brain system supporting spontaneous thought. Subsequent neuroimaging tools that could measure cerebral blood flow provided support that the brain is indeed highly active during "passive" or "resting" states, including seminal work by David Ingvar who provided some of the first brain images of what would later be called the DN (Buckner et al., 2008). Ingvar and others speculated about a "hypofrontal" brain state—a phenomenon that remains popular in current theories of creativity—characterized by reduced activation within the frontal lobes in the absence of external task demands and a corresponding increase in spontaneous cognition.

In the mid-1990s, cognitive neuroscientists were questioning the appropriateness of using the "resting state" as a control condition. A common finding across many studies was that the same set of brain regions showed "deactivation" compared to a wide range of goal-directed tasks. (It is important to note that the term "deactivation" is relative to the cognitive task of interest, such as reading, solving math problems, or engaging in a language task.) The pioneering work of Nancy Andreasen, who was interested in understanding the neural basis of autobiographical memory, provided compelling evidence that this control condition was misguided. Indeed, by including a novel control task that did not require rest or memory retrieval, she revealed similar activity within the DN during memory retrieval and at rest compared to the control condition. The common engagement of the same brain regions during memory retrieval and rest strongly suggested that common cognitive processes were engaged—namely, internally-directed and self-referential cognition characteristic of autobiographical memory retrieval. The realization among neuroscientists that the control condition of rest reflected important aspects of human cognition led to a paradigm shift in cognitive neuroscience, and the formalization of the network in a series of landmark papers by Marcus Raichle and colleagues in the early 2000s.

In the past two decades, empirical research on the DN has accelerated exponentially, with investigations examining the network's role in health, disease, and development. One of the major discoveries to follow the initial work came from the study of human memory. As noted above, the DN was implicated in autobiographical memory retrieval; subsequent work confirmed that the DN is reliably engaged during a variety of tasks that require participants to recall detailed episodes from their personal pasts. A critical extension of this research came from patients with lesions to the hippocampus—a DN region that plays a critical role in episodic memory retrieval—who showed difficulties imagining possible future events. This observation by Endel Tulving and colleagues raised the prospect that the same region or network supports both memory and imagination. A series of functional brain imaging studies provided compelling support for this theory: recalling past experiences and imagining possible future experiences showed

a consistent pattern of overlap within the DN. The constructive episodic simulation hypothesis was thus proposed by Daniel Schacter and colleagues: the notion that both episodic memory and future simulation are constructive processes that require one to flexibly recombine episodic details (e.g., people, places, and actions) to reconstruct past experience and construct plausible future experiences.

Memory, Imagination, and Creativity

Having briefly described the DN's discovery, we now turn to a discussion of its potential relevance to creative thought. In recent years the network has been implicated in a diverse range of creative tasks, from imagining new uses for objects (Kuhn et al., 2014) to assessing the aesthetic quality of artwork (Vessel, Starr and Rubin, 2012) to creating new music (Limb and Braun, 2008), poetry (Liu et al., 2015), and visual art (Ellamil et al., 2012). On the one hand, one might expect the DN to play an important role in creative thinking, considering the network's association with cognitive phenomena like self-reflection and mental simulation, which are often considered to be components of creative thought. On the other hand, because the DN is strongly engaged during memory retrieval—and creative thinking is thought to require generating ideas and solutions that transcend knowledge—one might expect the DN to constrain the creative thought process by activating what is already known. Indeed, this apparent paradox captures an active line of inquiry in modern creativity neuroscience that aims to understand how and when the DN contributes to creative cognition.

As discussed, the DN is commonly engaged during both episodic memory retrieval and future imagination tasks, indicating that constructive episodic processes support both remembering and imagining. These constructive operations of the episodic system seem to share some overlap with creative thinking, which is commonly considered to involve the flexible recombination of elements stored in memory. Such elements are often thought to be units of semantic memory (e.g., facts, knowledge, and physical features), but recent behavioral research has begun to show links between creative thinking and episodic memory (i.e., memory for personal past experiences). For example, Schacter and colleagues have found that an episodic specificity induction (ESI)—brief training in recalling a recent event in as much detail as possible—can improve performance on classic tasks of divergent thinking. Indeed, following ESI compared to a control induction, participants generate more ideas (higher fluency) that come from more conceptual categories (higher flexibility; Schacter and Madore, 2016). Notably, ESI does not appear to impact the originality of ideas, suggesting that its benefits are specific to increasing generative processes. These findings point to a greater role of the episodic system in creative thinking than has been previously recognized by creativity research, which has largely focused on semantic memory.

Until recently, neuroimaging research has provided only indirect evidence for the contribution of the episodic system to performance on various creative tasks. Activation of DN regions, such as the posterior cingulate and hippocampus, has been reported in several fMRI studies, ranging from divergent thinking to creative drawing. These studies, however, tend to show widespread activation of many other brain regions when contrasting a complex/creative condition (e.g., musical improvisation) with a simpler/noncreative condition (e.g., recalling melodies). Although informative, the selective involvement of specific cognitive processes such as episodic memory or mental simulation is difficult to discern in such designs.

To examine the neural basis of episodic processing during divergent thinking, a recent fMRI study administered the ESI prior to performance on an alternate uses task (AUT; Madore et al., 2017). Consistent with the behavioral study mentioned above, the authors found that ESI increased the fluency and flexibility of ideas generated in the AUT. This enhanced behavioral effect corresponded to increased activation within the left anterior hippocampus, which is consistently involved in episodic memory and simulation. Further evidence for the involvement of the episodic system comes from a study that directly contrasted neural activation during episodic memory retrieval, future simulation, and divergent thinking (Beatty et al., 2018). Compared to a semantic control condition, a conjunction of all three task conditions revealed common engagement within bilateral hippocampus. Taken together with Madore et al. (2017), these findings offer greater clarity on the cognitive processes associated with default activity during creative tasks, and they lend support to the notion that creative thinking involves the same flexible constructive episodic system as is engaged when one is remembering and imagining.

The DN has also been shown to support cognitive processes relevant for creative expertise, such as mental simulation (Meyer, Herschfield, Waytz, Mildner, & Tamir, 2019). In a series of experiments, Meyer and colleagues examined whether creative experts—in this study, a sample of professional writers, directors, and actors—are characterized by an enhanced ability to vividly simulate 'distal' experiences compared to their relatively less-creative but equally-successful counterparts (e.g., accountants, lawyers, and medical professionals). The authors reasoned that the groups would show comparable levels of 'proximal' simulation performance (e.g., "what will happen next week?") but that creative experts would show superior 'distal' simulation (e.g., "what will happen next century?"). This hypothesis was supported in two experiments: creative experts showed superior distal (but not proximal) simulation (i.e., they produced more vivid and detailed event descriptions). Interestingly, although creative experts and control participants both engaged the same neural mechanism for proximal simulation (the medial prefrontal cortex of the DN), creative experts more strongly engaged a different brain region during distal simulation (the dorsomedial subsystem of the DN). The results of this study suggest that specific DN regions contribute to cognitive processes relevant for domain-specific expertise, including the ability to vividly simulate experiences far-removed from the here and now.

Old and New Ideas

The involvement of the episodic memory system to creative task performance raises questions about idea novelty. That is, when people draw on memory to generate creative ideas, the ideas they come up with could be truly novel—i.e., generated on the spot, for the first time—or they could be simply recalled from memory. Indeed, a popular approach to scoring divergent thinking responses asks people to identify whether their ideas were ‘old’ or ‘new’ (Gilhooly et al., 2007). Behavioral research has provided evidence for the validity of this scoring method, including the finding that ideas labeled as ‘new’ by study participants are rated as more creative by independent raters than ideas labeled as ‘old’ (Benedek et al., 2014). Beyond its utility for creativity research, the old/new scoring approach provides a useful framework for understanding the role of memory retrieval and corresponding brain regions within the DN to creative cognition.

In a series of fMRI experiments, Mathias Benedek and colleagues examined neural correlates of old and new idea generation in the context of the AUT. The first study (Benedek et al., 2014) used a continuous idea generation paradigm during fMRI, where participants freely generated uses for different objects for 1 min at a time; they spoke their ideas out loud in real-time, and an experimenter recorded them so that participants could later label each idea as old or new. Both old and new idea generation were associated with activation of the right hippocampus of the DN, among other regions; new ideas compared to old ideas activated a region within left anterior inferior parietal cortex commonly associated with executive control. This research provided the first evidence that old and new idea production engage a brain region central to episodic processing.

Despite the intriguing findings of Benedek et al. (2014), a key issue regarding old ideas and memory retrieval was not addressed: namely, the distinction between recalling common object uses and recalling original object uses. Recalling common object uses should rely more on semantic memory (e.g., a car tire used for driving a car), whereas recalling original object uses that have been encountered but are not the common uses for the object (e.g., a car tire used as a rope swing) should rely more on episodic memory and corresponding regions with the DN (i.e., remembering a time when one saw a car tire being used as a rope swing). Indeed, in a follow-up study, Benedek and colleagues found that, compared to recalling common object uses, both the production of new ideas *and* the recall of original old ideas activated bilateral parahippocampal and medial prefrontal regions of the MTL and dorsomedial default subsystems, respectively (Benedek et al., 2018).

Despite the seeming importance of memory to creativity, the constraining effects of memory for creative problem solving are well-documented. Functional fixedness, for example, occurs when people have difficulty overcoming salient conceptual knowledge, such as being reminded of object properties in the classic Duncker’s candle problem. From a neuroscientific perspective, one might expect the DN to play a detrimental role in such contexts, in light of its contribution to memory retrieval. That is, although the DN has been shown to support the flexible combination of information stored in memory, the mere activation of specific items or concepts—such as those that are closely associated with a given cue or problem—may act as a source of interference that disrupts remote conceptual combination and idea production.

In a recent fMRI study, Beaty et al. (2017) examined the neural basis of conceptual interference during a verb generation task. Participants were asked to study a series of semantically-related noun and verb pairs (e.g., shoe-walk, phone-talk, hand-touch). The association between the noun and verb pairs was strengthened during a cued recall test, which presented the nouns and asked participants to recall the associated verbs. Then, during fMRI, participants were presented with either studied or unstudied nouns, and asked to “think creatively” to come up with a new verb that could be creatively linked to each noun; here, the studied verbs were expected to act as a source of interference when participants were generating new verbs to creatively relate to the studied nouns, i.e., the memory of the studied verbs should come to mind and impair idea production. At the behavioral level, the results confirmed this hypothesis: verbs generated in response to studied nouns were less semantically distant than verbs generated in response to unstudied nouns. At the neural level, this difference corresponded to increased activation within the posterior DN during the studied-noun condition, indicating that the memory of the studied noun-verb pair interfered with idea production by activating the DN.

Default and Executive Network Interaction

Mounting evidence implicates the DN in a wide range of creative tasks, raising the question of whether default activity alone is sufficient to explain creative thought. Although this brain system has shown activation in tasks ranging from divergent thinking to poetry composition, the findings of Beaty et al. (2017) and others suggest that the DN may not always provide the most original ideas, particularly when it activates memory traces that are decidedly unoriginal. Evidence from a growing number of studies examining how the DN interacts with other brain networks provides some clues as to how and when the DN supports and constrains creative thought. Instead of assessing activation of singular brain regions, these studies assess *functional connectivity*—the co-activation or correlation of multiple brain regions, presumed to reflect shared information processing between brain regions or some action of one brain region on another.

One of the most consistent findings to emerge from functional connectivity studies of creative thinking is an interaction between regions within the DN and regions within the executive control network (ECN). The ECN is also often called the frontoparietal control network because it consists of frontal and parietal brain regions implicated in several aspects of cognitive control, such as inhibiting habitual response tendencies, maintaining items in working memory, and switching between goals or mental sets. Importantly, the ECN tends to work in opposition to the DN: when one network is active, the other network tends to be inactive,

presumably due to their opposing cognitive functions (externally-directed control and internally-directed cognition, respectively). The involvement of the ECN in creative task performance is consistent with behavioral evidence that suggests executive cognitive abilities partly underlie individual differences in divergent thinking. These studies have found that people who are better able to manage and control their thought processes—e.g., people higher in working memory capacity or fluid intelligence—tend to perform better on creative thinking tasks, presumably because they can more effectively navigate unproductive lines of thought, such as when the DN activates unoriginal memory traces.

The notion that the ECN interacts with the DN to inhibit unoriginal ideas has received some support from recent functional connectivity studies. For example, in the creative verb generation study described above, Beaty et al. (2017) also found that, during the interference condition, a DN region showed increased functional connectivity with ECN regions. In other words, when the old memory trace of the studied verb came to mind—potentially reflected in DN activity—it needed to be inhibited for participants to come up with a novel association, and this inhibitory process was likely executed by ECN suppressing DN activity.

Other research suggests that inhibiting unoriginal ideas is not the only cognitive process associated with DN-ECN connectivity. In the episodic induction study of Madore et al. (2017), which reported activation of left anterior hippocampus during divergent thinking following episodic induction, the authors also examined functional connectivity and found that a hippocampal cluster showed increased connectivity with a frontal ECN cluster following the induction. This finding was interpreted to reflect the involvement of a goal-directed memory retrieval strategy promoted by the episodic induction; in other words, the ECN may couple with the hippocampus/DN to facilitate the strategic retrieval and combination of episodic content from memory. Taken together with the semantic interference fMRI study of Beaty et al. (2017), it appears that the DN may be a necessary but not sufficient neural substrate of divergent thought: the DN may require the ECN to manage and direct complex memory retrieval and combinatory processes that do not always guarantee the production of novel and useful ideas on their own.

At the individual level, a growing number of studies have found that creative thinking ability is characterized by stronger functional connections between the DN and ECN (for a review, see Beaty et al., 2019). In one recent paper, the strength of functional connections between DN, ECN, and salience network regions (a network involved in switching between the DN and ECN) was found to reliably predict a person's divergent thinking ability (Beaty et al., 2018a,b). This suggests that more original thinkers can more readily engage brain networks that tend to work in opposition, as well as the corresponding cognitive processes relevant to creative thought.

Conclusion

The brain's default network was a major discovery for cognitive neuroscience. Since its discovery, there has been exponential interest in investigating its role in human cognition, with several studies confirming the network's role in memory and imagination. More recently, the DN has been linked to various aspects of creative thinking, and considerable progress has been made toward understanding how and when the network benefits and constrains creative thought. This work has expanded our conceptualization of the role of memory in creativity, as well as the contribution of cognitive control, which may be required to manage memory-based idea generation processes that alone do not guarantee the production of novel ideas. As a field, the neuroscience of creativity continues to provide a more refined and nuanced understanding of how the human brain generates creative thought. Going forward, the DN is likely to take center stage in this quest to map the creating brain.

As historical discussions show, scholars have been attempting to define creativity for several thousand years. For example, Ancient Greek writers argued that only poets can be creative, and that creativity must deal solely with imaginary beings and events. Any practical activity was seen as mere artisanship. Earlier ways of conceptualizing creativity have not vanished. Creative individuals are still seen by some writers as the recipients of messages from above, and true creativity is still sometimes thought to be of necessity useless, and thus to have nothing to do with practical or everyday activities. By contrast, in this entry creativity is examined in what Arthur Cropley called a 'down-to-earth' way. It is regarded as a normal aspect of human existence and the purpose of the entry is to bust the myths surrounding the concept of creativity by outlining its cognitive, motivational, personal and social basis.

The Psychological Basis of Creativity

Thinking Processes

In 1950, J. P. Guilford complained that existing tests of intelligence focused mainly on 'convergent thinking' (finding the single best answer to a circumscribed problem). He contrasted this with 'divergent' thinking, which involves generating new, original and unexpected answers. The 1950 article was entitled 'creativity' and, despite the fact that Guilford also stressed the importance of personality and products, creativity quickly came to be associated with divergent thinking. Other researchers have also concentrated on thinking processes: Well-known approaches include 'lateral' thinking, 'janusian' thinking (named after the Roman god Janus, who could look backwards and forwards at the same time), 'homospatial' thinking (ideas from different domains are brought together into the same space), 'biphasic' thinking (in a first phase uninhibited combinations of ideas are produced, which are then evaluated in a second phase), and 'tertiary' thinking (primary process and secondary process thinking in the psychoanalytic

sense are combined). Associational theories emphasize the linking of apparently unrelated ideas ('remote associates') or 'bisociation' (linking unconnected fields).

Metacognitive Processes

Generation of effective novelty thus depends on special cognitive processes such as branching out, generating alternatives, recognizing similarities, and making remote linkages. However, acknowledged creative individuals have emphasized the importance in doing this of heuristics such as construction of neural networks or set breaking. The processes may also be guided by, for instance, intuition – sensing that certain approaches offer more promise than others. This is greatly facilitated by possession of rules or guidelines for recognizing blind alleys from the start and avoiding them. Evaluation skills such as mental blueprints of what an effectively novel solution might look like make it possible to see that a particular approach is proving inadequate or to recognize that a solution is at hand. Thus, creative thinking processes are guided by strategies, hunches or rules of thumb – what is commonly called 'metacognition'. These include monitoring progress, redefining the existing line of attack where necessary, being aware of alternative routes, recognizing opportunities, or understanding the costs and benefits associated with possible changes. Kozbelt (2008, p. 232) referred to creative 'wisdom.'

The Paradoxical Personality

A number of writers – such as Hans Eysenck – have emphasized the importance of personality in creativity. Reviews of the relevant research typically list characteristics such as flexibility, openness, sensitivity, autonomy and ego strength. Nonetheless, it has not proved possible to identify a specific personality profile that is typical of all creative people and also distinguishes them as a group from non-creative people. Striking in the discussion is that the personality characteristics regarded as important for creativity are sometimes contradictory: for instance, the creative personality seems to be simultaneously stereotypically masculine (autonomous, self-confident, tough) and yet stereotypically feminine (sensitive, intuitive, responsible). Thus, creativity requires a paradoxical personality characterized by polarities such as openness combined with drive to close incomplete gestalts, acceptance of fantasy combined with maintenance of a strong sense of reality, critical and destructive attitudes together with constructive problem solving, cool neutrality combined with passionate engagement, self-centeredness coexisting with altruism, self-criticism and self-doubt together with self-confidence, and tension and concentration side by side with relaxedness.

Motivation

The generation of novelty requires not only appropriate thinking and personality, but also readiness to diverge, defy conventional opinions, or accept the risk of being wrong. In addition, creative individuals are affected by cognitive motives which derive from recognition of gaps in existing knowledge (incompleteness), a drive to round out recently emerging knowledge (development), and identification of contradictions in accepted knowledge (conflict/discrepancy). Albert Einstein, for instance, indicated that he experienced all three of these motivating forces, but at different times. A widely accepted idea popularized by Teresa Amabile is that creativity is based on intrinsic motivation: the wish to carry out an activity purely for the sake of the activity itself, regardless of external reward. Some researchers report negative effects of extrinsic motivation, to be sure, but others claim positive effects, and still others report mixed effects. Kerrie Unsworth argued that the effects of external vs. internal motivation depend on whether the problem is imposed from outside or is self-discovered.

According to Edward Necka's triad model, there are five classes of creativity motive: instrumental motives, playful motives, intrinsic motives, control motives and expressive motives. In contrast to the emphasis on intrinsic motivation, this approach argues that creativity can be a means to an end, for example a person might write a book in the hope of making money. At one particular time a creative person may be extrinsically motivated, at another intrinsically. The idea of a dynamically changing structure of creativity motivation is supported by the 'evolving systems' approach of Howard Gruber, according to which a creative product emerges as the result of a long process of development of knowledge, emotions and feelings, and goals.

Feelings and Creativity

Research on creativity and mood, such as that of Geir Kaufman, has shown that mood is a precursor to creativity, accompanies it, and results from it. Furthermore, despite the widespread belief that positive mood is necessary for creativity and negative mood is fatal, research indicates that there is a role in creativity for negative mood too. Positive mood facilitates free expression of ideas, but negative mood promotes accuracy and precision. Thus, both generative feelings such as the thrill of the chase when facing a challenge, excited anticipation when generating novelty, or satisfaction after achieving an effectively novel product, but also conserving feelings such as anxiety in the face of uncertainty, frustration when progress is impeded, or disappointment when a product is not validated, play a role in creativity.

The Changing Understanding of Creativity

The Importance of Products

Largely thanks to Paul Torrance, the 1960s were marked by a focus on creativity in education. Discussions in this era were also heavily influenced by humanistic writers such as Carl Rogers, Abraham Maslow, or Rollo May, who emphasized the beneficial effects of creativity on individual well-being, self-fulfillment, and similar factors. Anatoliy Kharkhurin and Charlene Tan pointed out that Eastern understandings of creativity give greater emphasis to authenticity – representation of the person's true inner self. Although humanistic writers recognized that achieving goals is as an important part of self-actualization (i.e. they did not ignore products), discussions of creativity came to be dominated by questions of recognizing and fostering creative thinking (process), and the purpose of fostering creativity came to be seen as promoting psychological health (person). The role of educators was then seen as providing an appropriate environment (press). Writers such as Robert Albert and Arthur Cropley explicitly stated that (at that time) it was too difficult to establish stable, objective criteria of the creativity of products.

However, other writers have emphasized the importance of products. Donald MacKinnon concluded that they are 'the bedrock of all studies of creativity,' while Sharon Bailin labeled efforts to study creativity without reference to products 'misleading' and 'dangerous.' Creative products are not confined to fine art, literature, performing arts, music, and similar artistic/aesthetic domains, but also includes fields such as business, manufacturing, technology, medicine, administration, education, even defense, anti-terrorism and law enforcement. The role of a physical product is particularly obvious in fine art or performing arts, science, engineering, architecture and the like, or in business, where a concrete product is the usual result of creativity, but the 'wrong' product may spell ruin. On the other hand, in some areas, such as mathematics or philosophy, immaterial products such as novel concepts or symbol systems are more usual. The two kinds of product are possible in all fields, and both may be identifiable in most creative achievements, concrete objects being more prominent or dominant in some domains, symbol systems in others.

Creativity is Transferrable

John Baer has argued convincingly that creativity is domain-specific: He concluded that it is more like expertise than like a general abstract mental capacity comparable to intelligence. It involves domain-specific abilities, knowledge, skills and techniques, which differ from domain to domain (See Domains of Creativity). Other findings show that this is true at both a more general and a more specific level. For example, abstract knowledge is perhaps more important in science, technique in music. However, both mathematical creativity and creative writing require mastery of a set of symbols for representing ideas, although the two symbol systems may be different, while the exact knowledge required for research on creativity is different from what is required in botany, although both fields require a knowledge base. Thus, there is specificity in creativity, but generality too. This point of view seems to be supported by the existence of prodigious polymaths who make creative contributions to several fields, some of them differing widely in the specific knowledge and skills they require. Examples are the Nobel laureates Bertrand Russell (creative in domains covering a spectrum ranging from mathematics to literature), Herbert Simon (economics to psychology), and Albert Schweitzer (theology to music) (See Polymaths).

The core idea of transferable creativity is that there are creativity-related thinking strategies, motives, attitudes, and aspects of self-image that play a role in all fields. Phenomena such as openness to the new, willingness to take risks, or flexibility are now increasingly being referred to as 'competencies,' for example by Judith Burton and colleagues. Unlike skills – which are specific to particular tasks and may quickly become outdated – competencies are general personal dispositions that transcend specific locations and specific eras. Epstein et al. (2008, p. 8) identified four core creativity competencies, which they called 'capturing,' 'challenging,' 'broadening,' and 'surrounding.' Slightly reworded for the purposes of this entry, these involve recognizing and seeing the value of novelty, self-confidence and risk-taking, making remote associations, and openness. The idea of transferable creativity is based on the argument that people who have become used to, let us say, trying a new approach, linking ideas from disparate fields or approaching the same idea from different perspectives in one domain will transfer these competencies to other domains.

Creativity Is Not Always Good

Pan Kampylis and Juri Valtanen pointed out that almost all definitions of creativity treat it as inherently good; as Aleinikov (1999, p. 838) put it: 'devoted to human welfare.' Aleinikov called this 'humane creativity,' which is 'helpful,' 'generous,' and 'unselfish,' while other writers such as Howard Gruber and Mark Runco referred to 'moral' creativity'. However, the existence of what Keith James called 'negative' creativity and Robert McLaren referred to as the 'dark side' – creativity that leads to bad results – should not be overlooked. Sometimes the negative results of creativity are accidental or even unforeseeable; for instance, the discovery of germs was hugely beneficial to humankind, but laid the foundation for germ warfare. Even where an undesirable outcome is foreseeable, negative creativity is not necessarily the result of deliberate evil intentions. Some people may even create evil despite generally having benevolent motives, for instance, because they are unable to, unaware of, or unwilling to anticipate the negative consequences of their work, deliberately or unconsciously blinding themselves to it. This may occur, for instance because of a lack of information, fascination with the work, or because they are deceived or coerced by factors like the prospect of money and fame.

However, creativity is also sometimes deliberately misused, for example in advertising, business, entertainment, politics, science and technology, social or work life, crime, war, or terrorism. Most obviously negative, however, is the deliberate application of creativity with the conscious primary intention of doing harm to others – 'malevolent' creativity. Such intentional negative creativity may sometimes be widely applauded, for instance by the victors in war, even though it is devastatingly negative for the losers.

Thus, it is necessary to avoid being carried away by a general euphoria about creativity, and to look at it in a more differentiated way (See Creative Destruction).

Fundamental Issues

Is Simply Being Different Creative?

Shortly after the Second World War, [Morgan \(1953\)](#) concluded that the only constant factor in virtually all discussions of creativity is novelty. However, subsequent discussions made the important point that novelty alone is not sufficient for creativity. It is possible to speak of 'pseudo-creativity,' which is novel only in the sense of nonconformity, lack of discipline, or blind rejection of what already exists. These properties may be observed in many genuinely creative people, and thus be confused with creativity, but they are not actually an inherent part of it. It is also possible to distinguish what can be called 'quasi-creativity.' This has many of the elements of genuine creativity – such as a high level of fantasy – but its connection with reality is tenuous. An example would be the creativity of daydreams. As [Runco and Jaeger \(2012\)](#) pointed out, genuine creativity requires two further elements over and above mere novelty. A product must be relevant to the issue at stake and must offer some kind of genuine solution, i.e., it must be effective. Otherwise every farfetched, outrageous or preposterous idea or every act of nonconformity would, by virtue of being surprising, be creative. Thus, creativity is nowadays widely defined as the production of relevant and effective novelty. What is meant by 'effective' may differ from, let us say, fine art to engineering to business. In the former case, criteria such as beauty may play a decisive role (i.e., form predominates). By contrast, an engineering product – let us say a bridge – must be capable of doing a specific job: Few people would acclaim a bridge that fell down as a triumph of engineering creativity (i.e., function is paramount). Thus, simple deviation from the usual is not enough on its own.

Can Everybody Be Creative?

Creativity involves producing something novel and effective. However, this raises the question for whom a product, process or idea should be new: for all human beings throughout history, for the society or the era of the creator, or for the creator alone? Requiring that products be new in all human history would mean that a person would not be regarded as creative if someone else somewhere else had had the same idea at some time or other. On the other hand, defining creativity in terms of the point of view of the person in question only would mean that total ignorance would guarantee creativity. In fact, the word 'creativity' is used to refer to products ranging from being novel only in the sense that they have recently come into existence, regardless of relevance and effectiveness – such as a child's drawing on what was until a few minutes before a blank piece of paper – all the way to great works that are widely hailed as enlarging human perspectives in some way not previously seen in all history. The former involve everyday creativity, the latter sublime creativity. Even in the case of sublime creativity, it is possible to distinguish between two ways of producing effective surprise: by means of new applications of existing principles ('secondary' or 'minor' creativity) or by development of new principles ('primary' or 'major' creativity).

A more differentiated approach in this connection is the distinction among 'levels' of creativity made by Irving Taylor: 'Expressive spontaneity' requires only the free production of ideas, without regard to their effectiveness or relevance. This has a role in some creativity training procedures such as brainstorming, and may well be helpful in the production of novelty, but may often lead to pseudo- or quasi-creativity and is not sufficient by itself for sublime creativity. 'Technical creativity' requires unusually high levels of special skills or techniques, for instance with words or paints or a musical instrument or other tools. Despite its importance in some creative activities (such as painting or playing music), technical skill is not sufficient as a universal definition of creativity. 'Inventive creativity' involves applying the already known in new ways, 'innovative creativity' requires expanding known principles, while 'emergent creativity' encompasses the development of new principles. As a general but not universal rule, children often show expressive spontaneity, but lack knowledge of a field or skill with tools or special techniques. In this sense they can be said to display creativity, but only in the form of expressive spontaneity.

In the 1970s the idea of creativity in the person who will never achieve anything creative was introduced into the discussion by John Nicholls. In the 1980s, Ruth Richards and colleagues emphasized the importance of 'everyday' creativity. Although they may not produce innovative or emergent creativity, a high proportion of adults engage in the production of (at least for them) new ideas or products, for instance in the course of creative hobbies, or simply in everyday life. Thus, it is certainly possible to speak of creativity as a widely distributed characteristic seen in large numbers of people. However, some creative products have a greater impact than others. [Kaufman and Beghetto \(2009\)](#) developed a terminology for differentiating among different levels of public impact: They referred to 'mini-c' creativity (generation of novelty that is meaningful and effective only for the individual who generates it), 'little-c' creativity (novelty that has an impact upon at least a few other people), 'pro-c' creativity (novelty that has an impact in a field and is recognized and admired in at least that field), and 'Big-C' (novelty with an impact that puts the person generating it into the history books). However, as [Guilford \(1987\)](#) himself pointed out, historically speaking only about two in every million people produce effective novelty with an extraordinarily high impact. The intensive study of Big-C creativity involves learning a great deal, to be sure, but not about very many individuals, and certainly not about schoolchildren, scarcely any of whom are or ever will be included in the two in a million. Thus, a focus on Big-C deflects attention away from the mini- or little-c of the remaining 999,998 people per million.

What Is the Role of Hard Work and Knowledge in Creativity?

James Austin studied the circumstances leading to famous breakthroughs that seemed to come by chance: examples include Charles Goodyear (vulcanization of rubber), Henri Becquerel (radioactivity), and Alexander Fleming (penicillin). Austin distinguished among four sets of circumstances: blind chance (the individual creator plays no role except that of being there at the relevant moment); serendipity (a person active in a field hits upon something novel and effective without actually looking for it); the luck of the diligent (a hardworking person eventually stumbles onto something); self-induced luck (special qualifications of a person—such as knowledge, close attention to detail or willingness to work long hours—create the circumstances for a lucky breakthrough). Case studies suggest that genuinely creative results require a combination of all four kinds of luck, which raises the question of whether it is a matter of luck at all.

In some case studies, acknowledged creators have reported that their creativity came from nowhere: For example, Henry Miller believed that the ideas for his writing came directly from the ‘celestial recording room,’ and Ray Bradbury reported that he received ‘lightning strikes’ from on high that had to be written down immediately. Probably the best known modern popular exponent of the divine origins approach to creativity is Cameron (e.g., 2002, p. 1). She asserted that creativity comes from God and emphasized the importance of ‘spiritual electricity.’ Such reports have encouraged the idea that hard work and knowledge are unnecessary for creativity, or even that the two are incompatible, and has led to the impression in some quarters that simply relaxing or letting ideas flow will lead to creativity. For example, Kawenski (1991, p. 264) reported that her students’ ‘romantic notions led them to believe that creative thinking consisted of just letting their minds waft about dreamily, waiting for the muse to strike them.’ Rothman (2014) argued that: ‘If you’re really creative, really imaginative, you don’t have to make things. You just have to live, observe, think, and feel.’

However, a number of researchers have confirmed the role of knowledge in creativity: The Canadian Intellectual Property Office reported in 2007 that no less than 90% of new patents are improvements of existing patents. What seems to involve serendipity may, in fact, be ‘quasi-serendipity,’ as Cora Díaz de Chumaceiro put it, i.e., finding something you have put a lot of effort into searching for at a moment when you are not consciously searching for it, so that it seems to come from nowhere. In fact, although Carl Hausman maintained that creativity is so novel that it has nothing to do with anything that already exists, the idea that creativity draws from a wellspring of knowledge was already well established prior to the modern era. For instance, in a study of inventors early in the 20th century Edwin Prindle concluded that they work with existing knowledge gained via past experience. More recent writers such as Sharon Bailin have concluded that novelty always arises out of what already exists. John Feldhusen and Donald Treffinger summarized this view by referring to the ‘knowledge base’ of creativity. In general, an apprenticeship of 10–15 years seems to be necessary for acquiring the necessary fund of knowledge and skills, even in the case of famous youthful prodigies such as Mozart, who, it is true, produced creative music in his teens, but started acquiring systematic knowledge of music at the age of four. Herman Simon and William Chase concluded that about 10,000 hours of intensive work in a domain is necessary for eminent creativity. It seems appropriate to adopt a modified version of an aphorism uttered by Thomas Alva Edison: ‘[Creativity] ... is 1% inspiration, 99% perspiration.’

The Danger of Expertise

It should be borne in mind, however, that knowledge is a two-edged sword. Some recent research has looked at the problem that, although working successfully in a field over a long period of time (i.e., acquiring a great deal of knowledge) can provide a knowledge base that can be manipulated to yield effective novelty, it can also produce tunnel vision that narrows thinking and restricts it to the conventional. In the absence of appropriate personal properties such as openness to the spark of inspiration, flexibility, or courage to try the new, the possession of a large fund of knowledge (expertise) can inhibit the production of novelty. Great knowledge is thus both the friend and also the foe of creativity. Colin Martindale described the relationship as curvilinear: Too little knowledge is bad for creativity, but so is too much. In order to achieve effective surprise, experts need to be thoroughly familiar with the contents of their field but capable of seeing these in a new light. Creative experts often show a freshness and openness that is more typical of beginners: Robert and Michele Root-Bernstein described the ‘novice effect,’ which is seen in experts who are able to break out of the straitjacket of their expertise and look at their subject with the openness and freshness of beginners.

Creativity and Intelligence

Early in the post-Guilford era creativity and intelligence were often treated as rivals or competitors. However, convergent and divergent thinking correlate around 0.5, and studies of achievement have shown that, by and large, those students are most successful who display both creativity and intelligence. Research on, for example, engineers rated as creative showed that they display a combination of both creativity and intelligence. Thus, the two are separate but also related. Various conceptualizations of this simultaneous sameness and difference exist (e.g. the threshold theory, the overlapping skills approach, the components model). Liam Hudson concluded that creativity and intelligence are best understood as two contrasting styles for applying a general mental power, while Michael Wallach and Nathan Kogan referred to ‘modes.’ Arthur Cropley specifically argued that creativity is not synonymous with the divergent style or mode, but depends heavily on convergent thinking too. In fact, the essence of practical, productive, down-to-earth creativity lies in combining divergence and convergence. In discussions of organizational creativity, the idea of switching modes or styles is well-established and is described using terms like ‘oscillation,’ ‘dynamic shifting,’ or ‘mental ambidexterity.’

According to the threshold model, a minimum level of intelligence is necessary before creativity is possible. A slight extension is the idea that as intelligence approaches this threshold (corresponding to an IQ of perhaps 130) from below, the possibility of creativity rises, whereas when intelligence lies above the threshold, increases in intelligence have no consequences for creativity (i.e., IQ and creativity are uncorrelated once intelligence is high enough). This view has been expanded by the idea of a 'one way' relationship between creativity and intelligence. Intelligence determines the upper limits of a person's ability to obtain and store information, without actually being itself part of creativity. The degree of creativity depends upon the amount of divergence displayed in the processing of the information made available by intelligence. An approach even more clearly oriented towards information processing is the idea that intelligence involves channel capacity: Creativity arises from flexible and versatile handling of the information delivered by the channel to generate novelty, lack of creativity results from use of this information to yield orthodoxy.

A different way of looking at the issue is the overlapping components approach. For instance, Robert Sternberg identified six 'facets' of creativity: knowledge, insight, intrinsic motivation, the courage of one's convictions, special personal factors such as flexibility and willingness to take risks, and relevance. Some of these facets are shared by intelligence and creativity, with the result that the two are correlated: for instance, as has already been shown, knowledge is indispensable for both a high IQ and also for creativity. Other facets, by contrast, may be favorable for one but not for the other: Flexibility and risk taking may even detract from performance on an IQ test. Insight, which seems to be involved in creativity may be favorable for intelligence without being absolutely necessary. Intrinsic motivation is favorable for the acquisition of knowledge, but it is possible to operate rapidly, accurately, and logically without it, whereas it is believed to be particularly helpful for creativity. To the extent that they share facets, creativity and intelligence are correlated. Summing up, it can be said that creativity and intelligence are neither identical nor completely different (See Intelligence).

Creativity and Problem Solving

Especially in psychology, problem solving is often discussed in cognitive terms or as a special form of information processing. In conventional problem solving, the person solving the problem knows that it exists and understands the nature of the problem, intends to solve it, possesses special knowledge, some or all of which is required to solve the problem, and knows, at least in a general way, what broad form the solution will take. However, creative problem solving is required when one or more of the elements just mentioned (knowledge of the problem, of the means of solution and of the nature of the solution) is missing. In other words, creativity can be involved in problem solving but is not always necessary, while not all problem solutions are creative.

Thus, one way of showing the role of creativity in problem solving is to divide problems according to (a) their degree of definition; (b) the degree of familiarity of the means for solving them; (c) the clarity of the criteria for recognizing solutions. Clearly-defined problems that are solvable by means of standard techniques and for which there are obvious and well-known criteria identifying the solution constitute 'routine' problems. They can often be solved without the help of creativity, although when existing knowledge is applied in settings where it has previously been treated as irrelevant, a certain 'technical' or 'inventive' creativity occurs. By contrast, some ill-defined problems require, in the first instance, becoming aware that there is a problem at all, defining it, working out techniques for solving the problem, and developing criteria for recognizing a solution. Such 'complex,' 'intractable' or 'wicked' problems demand a high level of creativity. It is possible to distinguish between recognizing problems that are already evident in the present organization of available information and are obvious to any qualified observer, discovering hidden problems as a result of an intensive analysis of a situation, and inventing problems that are only apparent after the available information has been reorganized: Michael Mumford and associates refer to processes such as problem construction, information encoding, category selection, category reorganization, and category combination. A number of researchers see discovering or inventing 'good' problems as the vital step in creativity (See Problem Finding and Problem Solving).

State and Phase Models of Creativity

The idea that creative products result from the interaction of intelligent and creative styles of thought raises the question of how this interaction is organized. Some researchers focus on the idea that it involves phases or stages, and the most widely cited phase model is based on the work of Graham Wallas from nearly 100 years ago. Although he initially identified seven phases, it has become customary to speak of a four-phase Wallas model involving Preparation (a person becomes thoroughly familiar with a content area), Incubation (the person churns through this information), Illumination (a solution appears), and Verification (the person tests the solution thrown up in the preceding phases). The phase of Incubation is the subject of particular disagreement among researchers. It is intuitively obvious that creativity requires processing of information. However, Dean Simonton highlighted the disagreement among more recent theorists and researchers about whether such processes involve incremental improvement of an initial solution in a sequential series of orderly steps (more like the conventional idea of intelligence), or are chaotic and more or less random (more like the conventional idea of creativity). The first version of incubation involves 'monotonic' sequential refinement (polishing) of a single preliminary solution, step by step, each step improving the result of the previous step until the final form is reached. The second version involves many possible solutions popping up more or less complete out of the seething cauldron of ideas, until one is recognized as better than the others and survives through a Darwinian process of survival of the fittest.

Resolving the Paradoxes of Creativity

Creative individuals seem to combine apparently contradictory or even incompatible factors including thinking processes (e.g., divergent vs. convergent thinking), personal motivation (e.g., intrinsic vs. extrinsic motivation), and personal feelings (e.g., thrill of the chase vs. fear of failure). Colin Martindale described this as involving moving backwards and forwards between poles, and labeled it 'oscillation.' The phase approach suggests that both poles of the paradoxes are of central importance, but not simultaneously – states and processes like divergent and convergent thinking, intrinsic and extrinsic motivation, thrill of the chase and fear of failure wax and wane in importance depending on what phase of the innovation process is currently active. David and Arthur Cropley developed an expanded phase model, which splits Preparation into Information (cognitive aspect) and Activation (motivational aspect) at the very beginning and adds Communication and Validation (social aspects) at the end. In practical settings the process can be broken off early, for instance when evaluation of the product to date indicates that it is a failure. It can also start part way through, for instance when a person returns to an earlier partially worked out solution. It also function as a kind of spiral in what Melvin Shaw called 'loops'; for example, new information could make it possible to verify a novel solution that had earlier been rejected. Other writers such as Alexander Bain, Hermann Helmholtz, Henri Poincaré, and Jacques Hadamard identified and named stages (see for example [Sawyer et al., 2003](#)), and more recently the father of brainstorming, Alex Osborn, and Dean Simonton have also suggested phase models.

Creativity and Environmental Pressure

The Social Rules of Creativity

Creativity requires doing things differently from the way they are usually done, or even defying the norms of society, what Robert Sternberg and Todd Lubart called 'contrarianism' (although they were writing about giftedness in general, and not specifically creativity). Thus, creativity can be seen as involving a failure to conform to the norms of society. Societies are prepared to tolerate this to a certain degree, which rules can be broken or how large a deviation is accepted varying from society to society and from time to time, as well as according to the age, social position, occupation, and other characteristics of the individual doing the rule breaking. People publicly acclaimed as creative break the rules, but succeed in staying within acceptable limits. If they do not, they are likely to be regarded as eccentric, immoral, mentally disturbed or criminal rather than creative, with the possibility of being criticized, shunned or even locked away.

Research suggests that, as a result of the issues just outlined, creative people often need the support of advocates or facilitators. Some facilitators energize, activate or release creativity in others, without necessarily producing effective novelty themselves. An important function of such people is to offer creative individuals a safe space where they can break the rules without sanctions, as well as to offer them a positive perspective on themselves, for instance the view that their ideas are not crazy but creative. This recognition can help to foster the courage to deviate from what everyone else is doing, among other things by offering an opportunity to test the limits of the acceptable without risk or feelings of guilt. Creativity facilitators can be unsung people, such as a grade school teacher. In mature workers, such as scientists, working in a team may provide contact with facilitators. The groups of which a person is a member, either intimate groups such as the family, more public groups such as friends, or more or less formally defined groups such as experts/critics, colleagues, or employers can also foster creativity by offering a social environment marked by recognition and encouragement (or, of course, hinder or block it by withholding such positive feedback). Some researchers regard exposure to social support in a supportive (congenial) environment as the crucial factor in the emergence of creativity (See Friendships and Social Networks).

Socio-Cultural Validation

To have an effect or be recognized as creative, a product must thus not only be novel, but must also be communicated to other people and, most important in the present context, be accepted or at least tolerated by them. This acceptance involves what Csikszentmihalyi (1996) called 'socio-cultural validation.' According to this view, creativity is not really a property of products or processes at all, but a category of judgment in the minds of observers, often acknowledged experts or specialists. In some areas the rules for applying the label 'creative' are well established, with the result that there is a high level of agreement, not only among judges, but also between experts and members of the public. In other areas, however, there is less agreement, with the result that there are often controversies, for instance over the quality of a painting or a piece of music, the creativity of a new building, or even the acceptability of a novel law-enforcement procedure. Emphasis on acceptance by observers not only stresses communication, but also defines the final step in the emergence of a creative product: validation by the surrounding environment.

Innovation and Creativity

In the relevant psychological literature on creativity in business and industry the emphasis is mostly on innovation, rather than creativity. The difference is that innovation requires not only creating novelty, but also putting it into concrete practice in a particular setting. Thus, in a certain sense, creativity can be seen as a prerequisite for innovation or as a stage or phase of innovation. Several definitional problems are easy to solve in the framework of innovation, for instance the question for whom novelty should be surprising, relevant and effective, or the issue of chance. Innovation requires the deliberate introduction of ideas, products,

production and marketing processes, and the like, that are novel for a work group or an organization into which they are introduced. Usefulness in the sense of innovation is often easy to judge: production rises, sales improve, costs sink, absenteeism or staff turnover falls, or accidents in the workplace occur less frequently, to give some concrete examples.

Innovation can also be seen as a process having two phases. In the initial ideational phase ideas emerge that are new for the setting in which they occur. These ideas can be novel in an absolute sense (i.e., involving innovative or emergent creativity), but they need not be: For instance, a manager could make suggestions based on standard practice at a former place of work, novel only in the new workplace. Applying the already known in a new setting constitutes a creative act (inventive creativity), but only involves minor or secondary creativity. After this ideational phase comes the behavioral phase, in which the novel idea is put into practice. Creativity may occur without the behavioral phase, but this phase is essential for innovation; thus, innovation imposes a 'usefulness imperative' on creativity (See Innovation).

Researchers have described aspects of the organization that facilitate or block innovative behavior; among these are freedom to make decisions, support from close colleagues, and facilitating attitudes or other qualities of managers (e.g., leadership style). Inhibiting factors include negative aspects of the organizational climate, negative attitudes and leadership style of superiors, and inhibiting structure of command. In the case of the individual person, innovation often demands not only acquisition of new skills, but also changes in thinking strategies, the organization of knowledge, or ways of evaluating work activities. These can conflict with the norms of a particular setting, with resultant uncertainty or anxiety, and may have consequences for the self-concept. Thus, personal competencies interact with the characteristics of the organization to facilitate or inhibit innovation and to moderate its psychological consequences for the people involved.

Concluding Remarks

A common misunderstanding in psychologically naïve discussions of creativity is that it is an unknowable, indefinable force. In fact, as has been shown above, in modern discussions there is substantial – even if not universal – agreement that it is a psychological characteristic of human beings and not, for instance, a message from higher powers. Admittedly, the precise details of the cognitive, motivational, personal and social components of creativity are still the subject of discussion: For example, is it always good, must it be useful, do creative ideas emerge in a step-by-step linear sequence or do they bubble up from a fermenting cognitive brew, are there cognitive short cuts, is creativity general or specific, are the psychological foundations of creativity the same regardless of the level of public acclaim of products? Nonetheless, the age of ineffable, inscrutable creativity is passing away.

Introduction: A Roadmap to Creativity Development

Understanding creativity as it develops is one of the most critical topics for creativity research as new findings can help cultivate the fulfillment of creative potential throughout the lifespan. Synthesizing this line of work is however challenging for at least two reasons. First, as duly noted by [Guilford \(1950\)](#) “creative people differ considerably in performance from time to time” (p. 445). In other words, creative productivity and performance is not expected to develop linearly within individuals. Second, creativity is not a unitary entity and observed trends can greatly vary according to the specific aspects of creative potential accounted for (e.g., divergent thinking vs. trait openness). Further, creative performance depends on the domains, tasks, and even stimuli used to assess creative performance ([Barbot, 2019](#)). These facts reflect the complex and multifaceted nature of creativity established in early conceptualizations and widely supported empirically since then. Therefore, one can expect distinct developmental trajectories and pathways for (1) different aspects of the creative potential accounted for (asynchronicity of development), (2) domains of creative productions or tasks at hand and (3) achievements in real-life creative endeavors.

In a nutshell, there is a common agreement that creativity development is grounded in the development of imagination, as manifested in early years, for example, in the playful pretense behavior of children (e.g., [Russ, 2016](#)). This development continues from early childhood to adulthood, following trends generally marked by discontinuities, such as performance peaks, slumps, and bumps (e.g., [Barbot et al., 2016](#)), followed by a progressive decline towards later age (e.g., [Zhang and Niu, 2013](#)). However, the picture of developmental trends from childhood to adulthood and even to elderly age is quite inconsistent with conflicting findings across studies ([Gralewski et al., 2016](#)). In an attempt to summarize the state of affair on research investigating the developmental trends in creative abilities and potentials, this entry will necessarily oversimplify the complexity of this phenomenon by highlighting the most characterizing features of key developmental periods, ranging from early childhood to elderly age. Concluding remarks will discuss methodological challenges as well as future directions for research on creativity development.

Developmental Trends in Creative Potential: A Snapshot of Key Developmental Stages

Early Childhood: Playing to Be Creative

Although we could trace the roots of creativity development partly in individuals’ genetic makeup and in utero life, it is widely recognized that the early years of life lay the foundation for creative thinking. [Russ \(2016\)](#), among others, stressed the importance of pretend play, as a specific type of play which provides the children with a “vehicle for the expression of many processes that are important in creative production” ([Russ, 2016](#), p. 22). Indeed, similar cognitive and affective processes are engaged in both pretend play and creativity. When children are playing, they use their imagination to make things up and generate ideas. The predictive power of pretend play on creativity has been supported by a few longitudinal studies showing that the quality of fantasy or role-play predicts creativity and facilitates imagination in creative tasks. That said, most studies in this line of work have focused on divergent thinking (DT) as a way to operationalize creative potential. The contribution of pretend play for other important factors of creative potential (e.g., openness to experience) is less known, except for few qualitative accounts focusing on eminent cases (e.g., [Root-Bernstein and Root-Bernstein, 1999](#)) (See Play).

DT has been the main focus of most developmental studies, notably because it can be measured from a very early age, and as a result, most of what we know about the development of creativity comes mainly from insights in DT research. For example, [Bijvoet-van den Berg and Hoicka \(2014\)](#) longitudinally assessed the DT of two-year-old preschool children through exploratory

behaviors involved in non-verbal alternate use tasks. They concluded an overall upward trend in DT development as well as profound individual differences in DT during preschool age, consistent with other findings in this line of work.

Childhood: Bumps and Slumps in Divergent Thinking Development

During childhood, most research attention was paid to temporary declines in creative abilities, known as creativity “slumps” (Torrance, 1968). Even though this discontinuity is acknowledged, much controversy exists with respect to the timing, duration, and domain-specific nature of those episodes of discontinuity. Further, DT remains the most common operationalization of creative potential in creativity slump research, and little is known regarding the development of other resources of the creative potential including non-cognitive factors (Barbot, 2019). In essence, work focused on school years has identified three periods of DT slumps. The first corresponds to the entry into formal schooling, at around age 5 to 7. The second, and surely most popular and controversial one proposed by Torrance was coined the “4th grade slump.” It refers to a temporary decline in DT that was observed in a range of studies, and not observed in a range of others (e.g., Said-Metwaly et al., 2019). Finally, a third period of DT slump was outlined towards the beginning of adolescence around age 12.

An entire volume could be devoted to the DT slump phenomenon, given the large corpus of research investigating it and the striking variability in study findings. However, a recent meta-analysis (Said-Metwaly et al., 2019) has greatly contributed to synthesize this line of work and to yield more definite conclusions with respect to its central controversies. From a pool of 2139 standardized means involving over 40,000 subjects (2nd to 12th grade) across 41 studies, three-level meta-analytic models supported three main findings. First, they confirmed an upward trend in DT performance from 2nd to 12th grades, with evidence of patterns of discontinuity. Second, there was no evidence of general (i.e., mean) fourth-grade slump across studies, but instead, a marked seventh grade slump corresponding to ages 12–13, or the identified third period of slump. Third, whether or not average slumps were observed for fourth and seventh grade periods, moderator analyses showed that variability of results were explained by a range of factors including domain and task considered, intellectual giftedness, gender, or country of origin of the study.

Few studies have also emphasized the limited rank-order stability in creative performance during childhood, with slightly higher rank-order stability estimates as the study samples get older. Together, and despite the overall upward trends outlined above, these results support a profound intra-individual variability in DT development during childhood, with a slightly greater rank-order stability in adolescence compared to childhood.

Adolescence: Specialization of Creativity Interests and the Brain

While children’s creativity may be mainly unintentional, during adolescence creativity gets more intentional. Further, creative abilities may become more domain-specific as adolescents develop their interests in particular domains of activities, devote time, and by this means, progressively develop expertise in those chosen ventures (e.g., Barbot et al., 2016). Relatedly, adolescence is also a time in which creative activities invested in childhood may be abandoned, whether by loss of interest in those activities, or through the influence of negative performance feedback (i.e., “mortification” of creativity; Beghetto, 2014). This idea has important bearings with respect to creativity development, because it outlines that, through their new interests, adolescents can actively, and purposely, shape the development of their creativity in specific domains or tasks (much in line with Scarr’s theory of development).

In a time of important neurobiological changes, including a pruning mechanism by which commonly used brain connections are strengthened and those that aren’t often used are eliminated, it is expected that the adolescent’s commitment to specific creative outlets will translate in a specialization of creative potential in those particular ventures. Consistently, Kleibeuker et al. (2016) linked developmental trajectories of creativity during adolescence to changes in adolescents’ cognitive abilities, processes and underlying brain functions. Across several studies with adolescents and adults monitoring neural activation while completing creative problem solving tasks, Kleibeuker et al. found that adolescents performed better than adults on experimental problems that require exploration, seeking alternative solutions and shifting between representations. In many respects, exploration skills are developmentally relevant in adolescence: one of the fundamental tasks of adolescence is forming an identity, which in many ways, involves an exploratory-DT process of consideration or reconsideration of who one is and wants to be. Relatedly, adolescence may be a critical time to incorporate creativity as part of the definition of oneself (i.e., creative identity; Karwowski and Barbot, 2016), and in turn, to cultivate this important part of the self for the rest of one’s life.

From Early to Late Adulthood: Towards Professional Creativity and Achievements

During early adulthood and adulthood, the development of expertise gains further relevance to potentially produce creative achievements at a professional level (i.e., professional creativity). In short, from initial interests - tracing back to childhood or adolescence up to early adulthood - expertise will be developed, especially when sufficient time-commitment and effort is engaged into a particular creative venture. This hypothesis is supported by an empirical demonstration among eminent composers (Simonton, 2000), which concluded that specialization (in this case, overtraining and overspecialization) or versatility (broad interests and “cross-training” across multiple genre) determine creativity development across the life span (See Composers). This “creative-expertise” hypothesis largely applies to everyday life and professional creativity in the general adult population, given the necessary contribution of domain-based knowledge in most creative pursuits.

Aside from work highlighting the increased relevance of expertise as a key ingredient of creative success in adulthood, there is also a small body of research on the development of DT and other key resources of the creative potential. While different developmental models are proposed for research on DT and creative potential in adulthood, the Peak and Decline Model has received particular attention. It suggests an overall growth of creative potential until one's late 30s until it gradually declines. This is consistent with research such as McCrae and colleagues' showing a curvilinear trend with an increase in scores until about age 40, followed by "systematic maturational declines" (McCrae et al., 1987, p. 136).

Elderly Age: Time to Be Creative!

Studies on creativity in the aging population started in the 1970s, and in this context too, they primarily operationalized creative potential with DT tasks. This body of studies generally indicates a decline in creative potential, consistent with declines that have been documented for most cognitive functions (Zhang and Niu, 2013). Both the speed of information processing or reaction time and the unwillingness to question conventions explain age-related declines in aspects of the creative potential. For example, McCrae et al. (1987) partly attributed the decline in different aspects of DT to reduced response productivity. Other studies showed higher scores on elaboration, integration and originality compared to productivity scores, suggesting that more time may be invested in the elaboration, or quality of responses, at the expense of the quantity of responses.

While declining cognitive functioning may explain some of the decline in DT and other aspects of the creative potential in later age, this age is also associated with the opportunity to invest more time commitment into creative outlets. Thus, lower creative potential could come along with greater creative participation and achievements. Creative participation could also gain relevance in light of its potential therapeutic effects. Research has shown the benefits of creative participation to facilitate aging by, for example, providing a sense of purpose, interactions with others, personal growth, self-acceptance and autonomy (e.g., Flood, 2007) (See Aging).

Conclusion

The snapshot of developmental trends offered in this entry illustrates that creativity does not develop by itself, but has to be cultivated by individual factors (e.g., interests), the social environment (family, workplace, and in particular, the school environment) and culture. The range of factors underlying creativity development makes its outcome difficult to predict. Not only does the developmental asynchronicity of important resources of the creative potential result in a varying "fit" between creative potential and specific task requirements over time, but it also remains uncertain whether individuals will use their creative potential at any point in time, and if they do, what the quantity and quality of their creative outputs will be. As noted by Simonton (2000), "*a work that brings its creator unprecedented acclaim may be followed by an embarrassing fiasco*" (p. 312). Not just because the creative quality of any creative pursuit partly resides in the eye of the beholder, but also because creativity is, by nature, an unstable entity. This instability challenges the assessment of creative potential as it develops. This adds to a longstanding issue in measuring creativity development. In essence, the main challenge is the use of either the same task, or alternate form tasks when measuring creative potential over time. Both approaches lead to undesirable biases complicating the isolation of the "true" level of creativity change over time (Barbot, 2019).

Although research on creativity development gained increased attention over past decades and progress was made with respect to a range of methodological and conceptual issues, it is still challenging to derive definite conclusions regarding developmental patterns of creative potential throughout the lifespan. To advance knowledge on this phenomenon, alternative assessments approaches combined with improved research designs are necessary for future studies that consider the multidimensional and multi-domain nature of creativity as it develops.

Glossary

Contrarianism Behavior that is intentionally different or opposite from what others are doing.

Deviance Different from what is typical; differing from the norm.

Eccentricism Tendency toward unusual and sometimes outlandish behavior that may contribute to original thinking or may result from it.

Negative Deviance The behaviors that are different from the norms yet do harm to the development of a group or organization.

Open-Mindedness Tendency to consider all options and tolerate or even appreciate different perspectives.

Positive Deviance The behaviors that are different from the norms yet can still make contributions to the development of a group or organization.

Psychosis Disorder characterized by a loss of contact with reality. Historically, it has also been called madness, insanity, or lunacy.

Tolerance Seeing the value in behaviors or ideas even though they are deviant.

Introduction

The word deviance may elicit various negative images. It may be true that, a deviant is often viewed as someone who is dissenting, bizarre, or in the extreme cases, someone who suffers from mental illness or even poses a threat to others. When viewed statistically, deviance is usually seen as a departure from the mean or another measure of central tendency. Dictionaries also define deviance as the departure from what people normally consider to be acceptable. Taken collectively, different views and literal definitions imply that deviance entails a departure or a difference from prevailing cultural, political, physical, behavioral, emotional, and psychological norms. Deviants are rule-breakers or offenders in our social life. People who dress in black on a hot sunny day, who score very high or low on a test relative to their peers, or who eat all of their food through a straw are all examples of being a deviant. Despite all the negative connotations of deviance, it is also necessary for societal and cultural evolution. In the Darwinian model of natural selection, deviance provides the variation from which adaptive ideas and behaviors are selected. In addition, individuals with a tendency to break rules are more creative. A lack of deviance within a group usually results in poor decision making and problem solving and a group tolerating and accepting deviance is healthy.

Positive and Negative Deviance

Although deviance is generally defined as the departure from the norms, it can be further categorized into positive and negative deviance. Positive deviance, also termed as constructive deviance, seems more counter-intuitive than negative deviance. It refers to the behaviors that are different from the norms yet can still make contributions to the development of a group or organization. It includes a variety of behaviors, such as taking charge, whistle-blowing, prosocial rule breaking, and counter-role behaviors. These behaviors are mostly ethical. Negative deviance, also termed as destructive deviance, refers to the behaviors that are different from the norms yet do harm to the development of a group or organization. It includes behaviors, such as not following the instructions of the supervisors, intentionally slowing down the work cycle, and committing petty theft. These behaviors are mostly unethical.

Besides the differences in the conceptualizations of the two types of deviance, the motivations behind the two deviances also differ. Positive deviants are engaged in deviant behaviors primarily because they are loyal to the group and committed to the long-term well-being and functioning of the group but are concerned about the opinions or behaviors of others in the group. The deviant behaviors are driven by the hope for better group norms and the improvement of the group.

For example, people who understand the harmful consequences of smoking would be at odds with other group members who are engaged in smoking. However, being deviant in the group aims to help other members understand the harms of smoking, thus benefiting the health of the entire group.

Positive deviant behaviors may also be motivated by moral convictions that people hold. They may express their views that are deviant from those of other group members who make racist or other inappropriate comments because their moral convictions keep them from doing the same. Engaging in positive deviance can also be motivated by the feeling of psychological empowerment. On the other hand, negative deviants are engaged in deviant behaviors because they may be dissatisfied with or angry at the organization and are disinterested in the benefits of the group. The deviant behaviors are driven by the rebellion against others in the same group or even the attempt to sabotage the group or the organization that the group belongs to.

Many factors influence whether a person is engaged in positive or negative deviant behaviors. One factor is individual characteristics, such as personality traits and feelings of group identification. People who are agreeable and conscientious exhibit fewer deviant behaviors. Those with high group identification are more likely to show more positive deviant behaviors than individuals with low group identification. Engagement in deviant behavior is also significantly affected by the environmental or situational factors. For instance, people tend to engage in negative deviant behaviors when the nature of the goal and the means for goal achievement are both malevolent. The forgiving actions of the leaders would increase positive deviant behaviors but decrease negative deviant behaviors. In addition, employees engage in more positive rule-breaking behaviors when they face high problem-solving demands.

There are many differences between positive and negative deviance. While negative deviants are more likely to withdraw in the face of challenges, positive deviants may persist in the efforts of changing the group norms. However, surprisingly, these two types of deviance share common characteristics. The two types of deviance are positively correlated among employees in workplaces. Both are negatively correlated with personality traits of agreeableness and conscientiousness as well as perceived organizational support but positively correlated with negative affectivity, constraints among organizations, and conflicts in individuals' roles.

Deviance and Creativity

Research on the personality correlates of creativity behavior implies a profile of creators that is in many ways similar to the definitions of deviants. They show unconventional behaviors, avoid entrenched ways of thinking, are dissatisfied with the status quo, set their own rules, take risks, reject limits imposed by others, are willing to try new things, and open new experiences and ideas. They seem to have less time to be courteous, often refuse to respect others' opinions, and tend to be critical of others.

Some characteristics of creativity are found to be closely associated with deviance. For example, originality, the most widely acknowledged aspect of creativity, assumes unusualness, uniqueness, or novelty. An original or new idea requires some sort of deviance. When we say someone is unusual in comparison to someone else, this typically means that person is different from a group rather than a single instance. That group represents the norm. You cannot be like the norm and yet unusual, unless you are unusual in one particular way but fit the norm in all others. Deviance is, then, assumed by unusualness, uniqueness, originality, and novelty—and at least one of these is required for creativity, though it may be a necessary but not sufficient condition.

The Scales for Rating the Behavioral Characteristics of Superior Students are often used by teachers to identify students' creativity. Creative students are described as individuals who are uninhibited in expressions of opinion, radical in disagreement, more open to the irrational in him or her self, nonconforming, and not afraid of being different. These behaviors are deviant from the conventional classroom practices and the traditional values of our social norms.

Although people generally value creativity, research on implicit theories of creativity and conventional wisdom both suggest that creative individuals and creative processes test norms, question authority, and push limits. Creative persons explore and often seek out deviance, suggesting that the distinction between creativity and deviance is often blurred and difficult to identify. Given the common connotations of the concept of deviance, it might be worthwhile to recognize the value of deviance (See Personality).

Deviance and Open-Mindedness

Creativity is often defined as a complex construct or syndrome, which implies that more than one trait and ability is involved, such as autonomy, nonconformity, or even deviance. These traits may interact with a person's open-mindedness, a fairly common personality trait of creative individuals. Perhaps creative people, because of their open-mindedness and willingness to consider other ideas and concepts, are more likely to accept the deviance of others (See Big 5 Personality Characteristics).

There is a possible functional connection between open-mindedness and deviance. Individuals may consider unconventional and even deviant thoughts and behaviors because of their open-mindedness. This is a critical notion in several ways. Not only does it help explain the relationship between deviance and creativity, it also suggests that open-mindedness may ensure that open-minded people are more tolerant and perhaps even appreciative of creativity and apparent deviance of other people.

For the same reason, one might expect a kind of Matthew effect found in other areas of creativity research, where those with something (in this case, the right combination of open-mindedness and originality) will obtain and generate even more of it. Perhaps parents who have those traits will model and value them, and thereby raise children who also have them. The tolerance supplied by the traits may subsequently generate increased creativity in others who are raised in the same environment. This may also lead to an increased distance between creative and uncreative individuals. It may also explain why there are expectations for creative persons, such as the stereotypes commonly held about artists and other unambiguously creative individuals and their eccentricities (See Mathew, Pygmalion and Founder Effects).

Deviance and Psychosis

Many distinguished artists, musicians, and writers were diagnosed with some kinds of mental illnesses, Adolf Wolffi, Lord Byron, Virginia Woolf, Edvard Munch, Victor Hugo and Jackson Pollock, to name but a few. Robert Schumann, who is one of the most productive Romantic composers of the 19th century, ended up his life in a mental institution. The world-renowned impressionist artist, Vincent Willem van Gogh, suffered from recurrent bouts of mental illness during the final two years of his life, which at last led to his suicide. This link also holds true for average population. For a group of children with manic-depressive illness, researchers found an unusually high proportion of special ability among them.

Many explanations for the relationship between creativity and psychosis are offered. One is from Hans Eysenck, who suggested that both the capacity for creativity and the tendency toward mental disorder result from the same "overinclusive thinking". It occurs when something that does not belong in one category or concept is included in it. At the extreme, this leads directly to psychotic ideation. The psychotic individual is viewed as out of touch with reality—a deviant, at least in thinking, and often in manifest actions. At other times, overinclusive thinking can allow individuals to find unusual but useful connections among ideas. In this way, it can lead to creative thinking.

Another alternative explanation is rooted in an "inverted-U" shaped relationship between creativity and psychopathology, which suggests that a moderate psychosis results in an increase in creativity while a severe situation may lead to a decrease. When individuals have moderate manic illnesses, the psychopathological symptoms lead to the high arousal of brain activity, which may stimulate people with millions of novel ideas. On the other hand, creativity is seen as a channel to relieve the psychological conflicts and emotional distresses.

The evolutionary hypothesis or Darwinian theory of creativity argues that the link between psychoses and creativity is the consequence of the genetic selection. The genes that are liable to suffer from mental illness become adaptive and are retained in human evolution when they show the positive aspect of creativity. In this sense, creativity is viewed as one type of "compensatory advantages" to psychoses in the gene pools.

However, researchers are still exploring the questions such as what kinds of mental illness are associated with what types of creativity and what kinds of creative people tend to experience psychoses. One of those explorations is from James Kaufman, who used the term "the Sylvia Plath effect" when he found that female poets were more likely to suffer from mental illness than other types of writers.

Deviance and Contrarianism

Creative individuals often choose between working within the old prototype and pursuing a novel but probably unacceptable framework. When they think creatively, they are often more intentional than the section above might imply. Sometimes it is a result of tactics or strategies. One tactic is the contrarian one: the individual ensures that his or her actions are original by intentionally doing what others are not doing. The economic metaphor is "buy low and sell high." This tactic suggests that creative individuals often seek ideas which may be out of fashion but still have potential to gain favor. They do not back down from their unpopular view in face of resistance, and later find an opportunity to sell high those ideas. This strategy works well because it does ensure originality, the most commonly recognized facet of the creativity complex. There are, however, two caveats for the contrarian tactic. One is that contrarianism can be used in a manner that is contrary to creative achievement. The other is that contrarian behavior is not necessarily creative. It will likely appear as deviance and for the same reason, it ensures originality. A contrarian tries to find the margin, tries to be an outlier, and is therefore trying to be a deviant in some sense.

Deviance and Eccentricity

People's antagonism to conventional values and entrenched ways of thinking assumes many forms. Eccentricity is one of them. In everyday life, eccentricity is shown explicitly either by absent-mindedness or weird behaviors, especially on trivial things. This may suggest that those eccentrics are more engaged with their own work but pay scant attention to things other than their devoted domain.

Eccentricity is a type of deviance that is often mistakenly associated with psychosis. While schizophrenia and other mental disorders usually lead to dysfunction, eccentrics tend to function well, albeit in ways that appear strange to most people. In both cases, the concept of freedom—to think and behave as one wishes—is present, but the exercise of personal freedom is less dysfunctional in the eccentric.

Studies of eccentrics tend to report that highly gifted individuals exhibit signs of eccentricity and that eccentrics are often creative. The relationship between eccentricity and creativity is hypothesized to hinge on the fact that individuals exhibiting both tendencies are individualistic and apt to go against established norms. Perhaps the most notable example of eccentric creativity is Albert Einstein, whose behavior was often described as erratic or eccentric (e.g., wearing slippers or pajamas to formal events).

Eccentricity has been found to be a predominantly Western phenomenon. This follows from the emphasis on rugged individualism and privacy rights in the Western world. But the evidence in support of the hypothesized link between eccentricity and creativity is very thin, with some research suggesting that eccentrics are not eminently creative and creative individuals may not necessarily be eccentric.

Deviance and Crime

Throughout history, many creative individuals have spent time in jails. This is not surprising because creativity is often perceived as a form of deviant behavior, which can frighten people and threaten established societal norms. The jail lives of many famous persons are good evidence of the conflict between creativity and conformity. At the extreme, creative people are willing to take risks and are nonconforming and their novel ideas are not in line with traditional, societal norms. It may be that some of these individuals do not fear change and are deviant in thoughts, which allows them to produce creative works and lead them to break social laws as well. A subtle distinction can be made between creators who were jailed because their creative activities were perceived to be threatening (e.g., Socrates, Thomas More, and Galileo) and those who saw a stint in jail as furthering their creative endeavors (e.g., Thoreau, Gandhi, and Martin Luther King, Jr.).

On the other hand, the difference between creativity and crime is hard to identify without referring to the product and press (e.g., the social context). Products that are socially useful can be considered truly creative, otherwise, they are the results of crimes. This is similar to Sternberg's opinion that creativity and intelligence need to be tempered by wisdom. In addition, researchers distinguish "negative creativity" from "malevolent creativity" due to the different intentions of the behaviors. Both are deviants in creativity research and may lead to criminal acts. But the former may not indicate evil-intentioned creativity and may suggest potential benefit for the society. One instance is that a person finds a novel way to enter and change the database of the bank where he is working. He does it not because he wants to destroy the database or steal the information from the bank, but just because he intends to improve the structure of the database. "Malevolent creativity", on the other hand, makes use of creative ideas but leads to deliberate harm to other people or the society as a whole. Some of the examples include creative accounting and creative financing, which imply the abuse of accounting and financial systems for personal benefits. It is also frequently seen in warfare and a striking example is the introduction of poisonous gas to the concentration camps during the World War II.

Over the past decade, the empirical evidence has made a link between creative individuals and prisoners. Some studies found that, like most criminals, creative people tend to be anti-social and creative people and criminals are both more likely to ignore authority and do things in their own way. Other research also showed that creative people and prisoners both share the common characteristic of impulsivity. Russell Eisenman has, however, investigated the creativity of prisoners and found little evidence that convicted criminals are more creative than non-criminals. To the contrary, Eisenman believes that prisoners are generally less creative than non-prisoners, although creative prisoners do exist. Much remains to be scrutinized about the relationship between creativity and crime.

Deviance and Drug Use

Creativity and psychosis are also related through the maladaptive coping strategies such as drug use. At first glance, considerable evidence linking drug use and creativity appears to exist. Many eminently creative individuals, including Ernest Hemingway, Edgar Allan Poe, Tennessee Williams, Jackson Pollock, John Belushi, and Eric Clapton, abused alcohol or other drugs. Potential explanations for the apparent relationship include creative individuals' penchant for risks, the disinhibitive effect of alcohol and other drugs on creativity, and the role of drugs in easing the stresses of the creative life (See Alcohol).

However, a deeper look at the issue raises serious questions about the relationship between drugs and creativity. First, while the deviancy necessary for drug use and creativity is often mentioned as a reason for suspecting a relationship, it is worth noting that the use of many drugs, especially nicotine and alcohol, is quite common and thus not dramatically deviant. Second, much of the

evidence supporting the presence of a positive effect for drug use on creativity is anecdotal in nature. Empirical research generally does not support a strong, positive, causal relationship between creativity and drug use. To the contrary, long-term use of alcohol, marijuana, and other drugs appears to have a negative effect on creativity. Even in studies which partially confirm disinhibiting effects, other factors appear to hinder the degree to which individuals capitalize on the production of disinhibited ideas.

But this does not suggest that creativity does not lead to drug use. Creative success often leads to the amassing of financial resources that increase the ability to obtain drugs. People may turn to drugs to alleviate the many stressors associated with creative activity. A relatively new hypothesis is that people who consider themselves to be creative may experience pressures to conform to social expectations for creative individuals' behavior. For example, a writer may react to stereotypical depictions of the "alcoholic writer"—stereotypes held by society and the other writers in the peer group—by using alcohol more frequently (See Drugs).

Conclusion

Deviance seems to be the only real dark side of creativity. However, the ideas and processes that underlies creativity can be used in many ways. Consider the anecdotes surrounding the lives of creative individuals such as Einstein, Poe, Kafka, Martha Graham, and others mentioned in this entry. Their deviant behavior was frequently considered outlandish or dangerous and threatened to overshadow their creativity. Their deviance was often such that only the most sympathetic friends and family members could tolerate it. Steven Spielberg's mother has observed that if she had known the typical means for dealing with her son's frequently bizarre behavior, the arts would have lost a major creative talent. Instead, she simply tolerated her son's deviant behavior and encouraged his creativity.

The role of deviance in creative individuals and creative work needs to be accepted for social progress. It needs to be tolerated or it will be lost which will result in losing an opportunity to enhance creative work and social progress. Indeed, regardless of the ambiguity of research on creativity and deviance, most researchers voice the same basic conclusion: tolerance for creative ability. More specifically, what is needed is (a) increased tolerance for seemingly deviant behaviors and (b) discretion about when to be deviant and tolerant and when not to be deviant and tolerant. Clearly, both can be taken to inappropriate extremes.

Seven Dimensions of Dialectical Thinking

Dialectical thinking starts with the ancient insight that knowledge results from a dynamic process on different levels. First dialectical thinking relies on an ever-changing process: "everything flows." Intellectual progress is based on stable knowledge that is in certain parts deconstructed and synthetically reconstructed in new ways. It employs the interplay of thesis and antithesis in a constructive way to achieve an elaborated synthesis.

Second, dialectical thinking systematically applies traditional knowledge to actual problems. In this process traditional knowledge gains new meaning and is creatively deconstructed. Vice versa, the actual problem-solving processes are enriched and —creatively contextualized.

Third, general principles are applied to individual problems. In this process general principles become a new form and individual problem-solution can achieve general meaning. In this process, the dialectical interplay of individual causes and general principles can lead to new and usable problem-solutions. This process takes place in creative persons as well as in societies. Dialectical thinking synthesizes single ideas with the wholeness of knowledge of the domain. The dialectics of construction and deconstruction lead to new purposeful constructions and take place in an interplay of materiality and spirituality.

Fourth, on a more complex level, theoretical principles are applied to practical problems in the creative process. In this process, theoretical principles can be enhanced and transformed as well as the practical solutions gain general significance.

Fifth, dialectical thinking is a communicative process. Dialectical thinking does not only occur in everyday life and culture but also in science. Even the interpretation of strictly evidence-based knowledge depends primarily on the historical and societal situation. Most prominently Sokrates and Platon showed that insight stems from dialogue. This does not only mean dialogue with the other but also the dialectical interplay of past and present experiences (see Holm-Hadulla, 2004). This fundamentally social nature of dialectic creativity also facilitates new impulses for coaching, counseling, and psychotherapy (Holm-Hadulla, 2017).

Sixth, dialectical thinking can trace dialectical structures in natural sciences, psychology, and cultural studies and mediate these different perspectives interdisciplinarily (Holm-Hadulla, 2013).

Seventh, dialectical thinking can reveal scientific aspects of myths and discover mythic aspects of science.

Background

Dialectical thinking is deeply rooted in our cultural memory. Since ancient times, the interplay of seemingly contradictory propositions and beliefs plays a major role in culture. Dialectics, e.g., between constructive and destructive forces in human striving, can be found in ancient Egypt; old China, such as Konfucianism; and India, for example, in Buddhism. Similarly, the Biblical comprehension of creativity as a constant battle between good and evil forces is a predominant concept in Western culture. From ancient Greek philosophies of Heraclitus, Sokrates, and Plato to the "classical" dialectic theory of Hegel, the seven dimensions of dialectical thinking described above are elaborated again and again (see Holm-Hadulla, 2011).

The most sophisticated account on dialectical thinking in modern philosophy stems from G. F. W. Hegel. Hegel showed that scientific and cultural progress shines forth through a continuous interplay of theses and antitheses that leads to new syntheses. His dialectics are highly regarded in society and politics up until today. In the classical period of European culture, creativity has been seen as a battle of constructive and destructive forces, for example, by the politician, scientist, and poet Goethe. In modernity, pop-stars like Madonna, Amy Winehouse, and Jim Morrison versified about the dialectics between constructive creativity and

destructive aggressivity. A prominent example is the song *Sympathy for the Devil* by the Rolling Stones. It demonstrates that the awareness and transformation of human destructiveness into lyrics, music, and dance is a major creative motivation (see [Holm-Hadulla, 2019](#)). This example illustrates how modern pop-culture also deals with the ancient dialectics of construction and destruction.

The following sections will show how dialectical thinking is not only relevant in cultural studies but also in psychological and neuroscientific concepts of creativity. Drawing on dialectical thinking, they present an interdisciplinary synthesis of cultural experiences and scientific results which leads to practical consequences.

An Interdisciplinary Synthesis of Creative Dialectics

The dialectics of order and chaos can be exemplified by the reciprocity of coherence and incoherence. In different scientific domains, the concept of dialectics carries different meaning. However, these diverse scientific concepts express a common ground which amplifies scientific perspectives through interdisciplinary interpretation. The dialectics between coherence–incoherence, stabilization–destabilization, and construction–deconstruction within cognition, motivation, emotion, and action are corresponding and complementary principles.

As a first step to an interdisciplinary dialogue, essential findings on the creative process of neurobiology, psychology, and cultural studies will be presented. Subsequently, the limitations of the individual scientific approaches and elaboration on corresponding and complementary findings of other scientific disciplines will be highlighted. For this purpose, descriptions of phenomena and guiding principles such as the dialectics of coherence and incoherence, order and chaos, and, phenomenologically speaking, intention and fulfillment ([Husserl, 2001](#)) are necessary. These descriptions are relevant in all sciences, but of different significance based on different theoretical, methodological, and interpretive requirements. In interdisciplinary mediation of the findings and descriptions of the individual sciences, there is a risk of improper use of terms since in every scientific domain these terms have different meanings. Ultimately, interdisciplinary dialogue must be established on its own by courtesy of usable concepts and practical consequences ([Gadamer, 1976](#)).

The premise is that interdisciplinary interpretation of psychological, neurobiological, and cultural findings will enhance understanding of creativity and leads to practical consequences. Focusing on the creative processes of everyday creativity which often are a precondition for extraordinary creativity ([Csikszentmihalyi, 1996](#)), the criteria of novelty and usefulness may serve as a preliminary definition of creativity which is yet to become more concrete in the description and analysis of the creative process ([Runco 2014](#)).

Neurobiology of the Creative Process

This section will attempt to demonstrate that innovative forms manifest themselves in the autopoietic activity of the brain which oscillates dialectically between coherence and incoherence. Furthermore, the argument will be made that the neuronal interplay of coherence and incoherence corresponds to psychological findings and cultural experiences.

In an evolutionary interaction between organism and environment, the brain has developed throughout the history of nature as an organ which establishes and maintains the organismic order by means of its fundamental function of integration. The brain hosts coherent perceptions and interpretations of events as well as meaningful action. Moreover, it supports a dynamic balance between information maintenance and flexible adjustment. Neuronal coherence, also described as “intra- and subcortical connectivity,” is a temporal relation of excitation in the nervous system (for detailed references see [Holm-Hadulla, 2013](#)). Such synchronicity of neuronal activity is likely to be the biological manifestation of lived experience and corresponds with the continuity and discontinuity of the stream of consciousness.

The temporal coordination of neuronal activity between different brain areas, measured, for example, with magnetoencephalography (MEG), is of interest for the understanding of the formation of ideas and the perception of emotions as well as goal-directed actions. The emergence of cortical connectivity—for example, between the hippocampus and prefrontal cortex—correlates with the emergence of coherent mental representations. For the understanding of creativity, it is vital to see how the brain integrates the apparent chaos of disordered emotions and perceptions into coherent impressions. There seems to exist a delicate interplay between stabilization and destabilization of cortical networks.

The lack of sufficient coherent neural networks and weakness of neural connectivity seem to be associated with mental disorders. In schizophrenia, for instance, it has been shown that no circumscribed brain lesion is critical, but rather a distributed impairment that involves the connectivity of different cortical areas. Some authors speak of a disconnection syndrome as a manifestation of disturbed coherence. This conception corresponds with the classical phenomenological view that mental incoherence is a characteristic trait and state in schizophrenic psychosis. In posttraumatic stress disorder and some depressive disorders, neural systems associated with emotions are disconnected from neural systems associated with cognitions. The therapeutic success in these conditions is accompanied with an increase in cognitive–emotional connectivity. This is consistent with the results achieved by cognitive-behavioral psychotherapy and psychodynamic psychotherapy. Different psychotherapeutics concur in their support of cognitive and emotional coherence ([Holm-Hadulla, 2017](#)).

Brain activity in general is characterized by a constant interplay between synchronization and desynchronization of neural activity that appears to be subject to a principle of coherence. The passive and active synthesis of conscious experience drifts toward a coherent association of experiences, for instance, in memory and expectation. Husserl speaks of a dynamic transition of intention

and fulfillment (2001). Basically, perception is not only dependent on sensory input but always corresponds with an empty horizon, for instance, when an individual does not see all sides of a dice at once but still is aware of its entirety. On this account, the synthetic forms of perception are not constituted by structures of mere static receptivity, but dynamic networks in process of formation, dissolution, and reformation. Such processes of construction and deconstruction can also be found on the molecular level.

It has been shown that the function of a cortical default mode and its reciprocal interaction with subordinated neural systems leads to organized coherent large-scale networks. The emergence of spatiotemporal order enables self-referential processing, autobiographical recollection, mind-wandering, and creative thinking. Functional connectivity enables the creation of novel and valuable emotions, cognitions, and actions.

In order to stabilize and adapt, the neural networks are constantly recalibrated. This occurs especially during phases of “random episodic silent thinking” (Andreasen, 2005). Andreasen portrays these phases of an undisturbed default mode of brain activity as particularly relevant for creative thinking. In these phases, traces of memory reorganize themselves and adapt to recently acquired content. This is done by continually changing patterns of activity in search of the most likely or plausible coherent models, up to the moment when the selective search turns into a result. It can be shown that these states, which correspond to psychological “illumination phase” of the creative process, are associated with particular first-person experiences, such as “flow.” Its apparent biological correlate is the activation of reward systems.

It is puzzling, however, why the states of cognitive consistency and emotional satisfaction are short and often will be replaced by new problem-solving processes which provoke dissatisfaction. This dissatisfaction associated with the destabilization of coherence resembles the subjective unease during the incubation phase and the demand to strive for new coherent forms.

As on the cognitive level, the dynamics between coherence and incoherence, and stability and instability also play a major role on the level of emotion and interaction. However, from a neurobiological perspective, it seems that some degree of incoherence favors cognitive and emotional activity. This would in turn correspond to psychological and phenomenological studies showing that a certain degree of emotional destabilization, anxiety, and depressed mood may enhance creative activities.

As a result of our neuroscientific considerations, we propose the following definition of the dialectic creative thinking: Dialectically creative thinking involves the synthesis of sensations in an interplay of coherence and incoherence. This process manifests itself in the dialectics between stabilization and destabilization of temporally synchronized or desynchronized neural networks. Thus, the autopoietic activity of the brain hosts the self-sufficient emergence of innovative forms.

In summary, new ideas are correlated with the emergence of new and coherent neural networks. Neuronal connectivity—especially between excitations localized and controlled in the amygdala, hippocampus, and prefrontal cortex—correlates with coherent feelings, thoughts, and actions. There is, as it were, a constant interplay of top-down and bottom-up regulation which leads to neuronal coherence. The destabilization of neuronal coherence which is often associated with unpleasant feelings reinforces the autopoietic activity of the brain to create and stabilize new neuronal patterns. Of practical significance is the finding that the autopoietic mode of the brain functions better when it is not impaired by permanent sensory input.

From an interdisciplinary perspective the question arises how the neurobiological findings and their interpretation can complement psychological creativity research and cultural knowledge.

Psychology of the Creative Process

Corresponding and complementary to neurobiological findings, the dialectical dynamic between coherence and incoherence is also found in psychological creativity research. Studies from cognitive science show that the dialectics of the creative process bring about gradual transformations and end when sufficient coherence has been achieved (for detailed references see [Holm-Hadulla, 2013](#)).

Developmental psychology describes how the dialectics of the creative process begin in early childhood. Various psychological studies show that creativity is associated with an interplay of seemingly paradoxical factors: Crystalline and fluid intelligence, convergent and divergent thinking, concentrated and freely associative thinking, persistence and flexibility, and openness and self-limitation. One can reinforce creative ideas by disciplined work and chaotic ecstasy, as well as by goal-directed and purposeless activities. Creative surroundings are described as strictly organized and freely disorganized at the same time.

Psychologically, the creative process depends on the following basic requirements: talent, knowledge, motivation, personality, and environment ([Csikszentmihalyi, 1996](#); [Runco, 2014](#)). Fluid intelligence may be a prerequisite of creativity along with specific forms of crystalline intelligence like linguistic, logical-mathematical, musical, bodily kinesthetic, spatial, interpersonal, and intrapersonal.

Talents are realized creatively by acting in a dynamic balance of convergent and divergent cognitions and emotions. These relations are akin to the reciprocity between convergent and divergent thinking. Convergent thinking is defined as focused, concentrated, and goal-directed whereas divergent thinking is less focused, associative, and directionless. These concepts match saliently with the neurobiological concept of the dynamical stabilization and destabilization in neural networks. Psychological analysis locates this dynamic process of the interplay of coherence, incoherence, and novel coherence within everyday creativity as well as extraordinary creativity. The notion of dialectics of construction and deconstruction is a further aspect of this relation: one destabilizes stable knowledge and common patterns of experience in order to create new and useful knowledge and patterns.

The motivation and decision to be creative takes place in the dynamic interaction between stable but no longer sufficiently useful solutions on the one side and the instability which precludes new results on the other side. Amabile (1996) and Csikszentmihalyi (1996) expanded the scope of creativity's prerequisites by different personality traits which apparently are in dialectical interplay: resilience and flexibility, concentration and openness to new experiences, conformism and nonconformism, and stability and tolerance of ambiguity. With respect to the practical creative processes, the dialectics between these factors seem to be an important guideline. Furthermore, the differences in the interaction of the psychological factors in different domains (cf. Runco and Richards, 1997, Runco, 2014) should be taken into account.

In addition to the complex interweaving of talent, knowledge, motivation, and personality traits, environmental conditions play an important role in the creative process. Similar to the neurobiological point of view, the psychological perspective additionally emphasizes the balance of disciplinary structures and free play areas (Runco, 2014). This change begins in early childhood and continues throughout life. "Interested and empathic guiding" is a term for the supportive function of caregivers which reinforces the talents and motivations of children in an emotionally assertive, but also intellectually competent way. Such guidance should strengthen the resilience to tolerate the dynamics of stability and fragility and foster the interplay of coherence and incoherence, and satisfaction and dissatisfaction throughout the creative process. The process requires the continuous balance between convergent learning and divergent playing. In other words, suitable environmental conditions are necessary to give a stable framework for the self-referential search for innovation.

The dynamic of stabilization and destabilization is shaped differently in special phases of the creative process. This dynamic takes place in the five phases of the creative process: preparation, incubation, illumination, realization, and verification (Holm-Hadulla, 2011). In the preparation phase, for some people it is difficult to patiently acquire coherent knowledge and stable skills because they lack tolerance of the uncertainty that they experience when faced with the yet unfinished creative destabilization and transformation of existing coherent knowledge.

The second phase of the creative process, called the incubation phase, can lead to similar difficulties. This phase is characterized by the fact that the task is set aside and left to autopoietic and often unconscious processing. Like the preparation phase, the incubation phase may evoke distress: After the acquisition of knowledge and skills by virtue of complex motivations, the individual anticipates preforms of creative achievements. He or she must now endure a certain degree of destabilization and incoherence. There is a frequent tendency to reduce the stimulating tension by reverting to previous customs or even manipulating the creative tension, for instance, with alcohol and drugs. Therefore, during the incubation phase, a capacity to let intuitions roam without tangible results as well as the patience to find the creative balance of purposeful activity and undirected autopoietic processes are mandatory (Andreasen, 2005).

The metaphoric term "illumination phase" refers to ancient myths and religious ideas as well as philosophical concepts in which creative inspiration is enabled by divine enlightenment. Psychologically, creative illumination rarely occurs as a sudden inspiration, but is usually a complex phenomenon which develops gradually. To capture the new cognitive, emotional, and practical situation, the dialectic between stabilization and destabilization, and convergent disciplined concentration and divergent associative awareness comes into play once more.

In the fourth phase, called the realization phase, the novel and useful forms are elaborated. Besides passion, curiosity, and originality, stability and resilience are required to endure the slow-paced progress of work and the disappointment that, despite illumination, the work yet remains unfinished. While the incubation phase may cause uncertainty through its lack of precise order and form, the realization phase requires one to renounce new ideas and to convergently form the new order as it had been envisaged in the illumination phase. For the sake of practical implementation, it is important to recognize the hazards of the individual phases of the creative process in order to effectively deal with them.

The last phase of the creative process, the verification phase, is of determining influence for the acceptance of the work in society. The properties of the creative product now acquire a special significance. Psychological categories can no longer grasp what is new, appropriate, useful, and unusual about a scientific idea, a poem, a picture, or a song. The fact that creative people often consider their product with destructive doubts and thus prevent new creative processes is a critical factor. Permanent feedback monitors the phases of the creative process. The reactions of others in the verification phase, for instance, shape the motivation to new preparations, the resilience in the incubation and illumination phase, and the productive realization of other works.

At each stage of the creative process, we can recognize the dialectics between coherence and incoherence, stability and instability, and order and chaos. In the preparatory phase, there is a prevalence of patient acquisition of knowledge and skills. Nevertheless, divergent and associative thinking and feeling are not meaningless, even though their meaning primarily relates to psychophysical regeneration.

The incubation phase is characterized by indefinite and incoherent forms, while in the illumination phase a new order and coherence suddenly occurs which may once again be destabilized by different ideas and emotions in the realization phase. Furthermore, the verification phase is a mix of stabilizing recognition and destabilizing (self-) criticism that can be both an incentive and an obstacle for the engagement with further creative processes. Thus, the creative synthesis which is achieved in the dialectic process does not exclude antithesis. On the contrary, actively conceiving multiple opposites and antitheses can enhance the creative process and lead to better results.

Also, in respect to opposing and even chaotic emotions one could hypothesize that eminent creative persons can endure incoherence better than their average fellow humans do. On the other hand, it seems, as Rorty (2001) summarized from an epistemological and practical standpoint, that, just like in their brain and mind, human beings can also tolerate incoherence in their everyday life only for a finite period of time.

Neurobiologically and psychologically it is undisputed that environmental conditions modulate information processing and recombination. However, although developmental and social psychology can explore factors that are conducive to creativity, they are limited in the exploration of complex cultural influences. Thus, to include the complex cultural conditions of creative processes, it is necessary to refer to cultural studies. This is also important because cultural narratives shape the interpretation and practical application of scientific results (Gadamer, 1976).

Cultural Aspects of the Creative Process

Cultural studies show that the destabilization or deconstruction of the usual orders of cognitions and emotions can lead to new knowledge and creative figurations (Assmann, 1995). One can assume that new and useful coherence emerges in a dialectical process between order and chaos. This explanation corresponds to psychological findings about the transformation of cognitive and emotional incoherence into coherence by creative thinking.

This section shows how the dialectics between coherence and incoherence in the creative process appear in cultural studies. Starting with an analysis of myths of creation can determine that dialectics between chaos and cosmos, i.e., “shaped order,” are dominant in classic narratives (see Holm-Hadulla 2011). In Greek mythology the gods are driven by constructive and destructive forces. For example, Kronos, in Latin called Saturnus, is an incarnation of constructive creativity but also of destructiveness. Following this concept, human beings are blessed with and condemned to permanent creative activity to maintain the order against the forces of chaos.

Similar concepts of creativity can be found in the traditional myths of India and China where divine and human creativity is connected with a permanent struggle between constructive and destructive forces. The implicit description of psychological and social relationships by Greek myths of creation had a strong influence on Greek philosophy which has itself continued to be relevant for Western thinking until today (Gadamer, 1976). The prevalent concept is that there exists a fundamental conflict between order and chaos, and stability and instability, which leads to creative activities.

The dialectic concept of creativity was most influentially formulated by Heraclitus, who emphasized that the world is kept in motion by opposing forces which coalesce into new forms breaking up once more into an endless flow. Particularly in the “*Politeia*”, his most extensive work, Plato wrote that education and culture should serve the goal of transforming the chaos of ideas and affects into coherent forms. Furthermore, he asserted that the community is threatened permanently by destructive forces leading to chaos which require constant creatively ordering activities. Struggle between constructively ordering and destructively disorganizing forces is a motif in Aristotle’s work as well. In a dialectic process chaotic energy and matter realize their potential in creatively ordered achievements (see Holm-Hadulla, 2011).

During the Renaissance, eminent artists, scientists, and politicians were regarded as particularly inspired because they bestowed ordered structure on unordered chaos. Creative potentials flourish in a struggle between constructive and destructive powers. Creative activity brings forth exceptional achievements but can also destabilize and lead to melancholy and despair. In the times of Idealism the whole human development was portrayed by aesthetic theories, for example, of Schiller as a creative task. Especially Hegel showed how individual, social, and political potentials are realized in conflicts of contradictory forces and interests. In the “struggle for recognition” the elaboration of conflicting interests leads to creative development, and social and political order. Hegel did not reduce dialectics to an intellectual operation of thesis, antithesis, and synthesis but conceived them as a way to shape human existence. Recognition becomes a central term in human ambition for new and useful forms. Hegel’s concept is consistent with modern developmental psychology showing the fundamental significance of the human need to be seen and receive responses. Even the most introverted creator needs some kind of recognition, at least by himself or herself.

A special elaboration of the psychological aspects of the classical concepts of individual and social self-realization can be found in Goethe who became one of the most influential statesman, scientist, and poet in Europe. In multiple autobiographical texts he described the close interweaving of emotional destabilization and cognitive disorder with creative achievements. His cultural, scientific, and psychological (self-) reflections lead to the complex idea of a permanent “dying and becoming” in the creative and self-therapeutic process. Interestingly, Goethe was not fond of the term “dialectics” but preferred the notion of “polarity” meaning the interplay of light and dark, and good and evil. Similar ideas can be found in the 20th century, for example, in the later works of Freud (e.g., 1920) which emphasized the importance of everyday creative activity that opposes destructive individual and social forces. In this context, the notion of “creative bipolarity” (Holm-Hadulla and Koutsoukou-Argyriaki, 2017) becomes relevant.

When it comes to the concrete social and political conditions of the creative process ethical aspects should also be considered. In 1942, the Austrian-American economist Schumpeter introduced the concept of “creative destruction” into the economic and political discourse on creativity. However, it was primarily instrumentalized as a justification for economically “unrestrained markets.” At the end of the 20th century creativity became a kind of magical phenomenon which should improve individuals and society. In this context, the term “creative class” was coined in order to describe the social circumstances that guide policies, economy, and culture. This view became very popular until the financial crisis of 2007 dampened the optimism of economic creativity and showed the dangerous side of short-lived innovations.

Conclusion

Dialectical thinking shows that real creativity is never destructive; in contrary it is transformation of destructiveness. This can be seen in politics and social life as well in the individual experiences in consulting, coaching, and psychotherapy. Thus the seven dimensions of dialectical thinking described above work together and lead to an enhanced recognition of reality. Productive communicative processes start with the acceptance of change (1) where traditional and learned personal and social concepts become fluid (2). General principles are applied to individual cases while both gain new significance (3). This is reflected in dialectics of theory and practice (4). Dialectical thinking in consulting, coaching, and psychotherapy is a communicative process (5) that can lead to novel and useful constructions of internal and external reality. Dialectical thinking helps to deconstruct dysfunctional meanings and beliefs not only in personal and social life (6). In science, dialectical thinking can detect cultural patterns in the interpretation of empirical results as well as enhancing cultural wisdom by scientific investigations (7). Myths like “selfish genes,” “bliss molecules,” or “love hormones” ought to be reflected dialectically in the dynamics of real life (*Lebenswelt*). Thus, phenomenological and dialectical psychology can provide a foundation for the interpretation of laboratory results (e.g., [Wendt, 2018](#)).

When using dialectical thinking in consulting, coaching, and psychotherapy, cultural differences in the configuration of order and chaos come into play. In Western cultures uniqueness and individuality of the creative act are emphasized; in Eastern cultures collective and repetitive aspects of creative processes stand in the foreground. The first verb of the Bible, “creavit,” denotes an individual and unique act that gives the chaos structured form while the classical Chinese term “zaohua” refers to a collective and continuous process of transformation of the preexisting state in order to control chaos and destructiveness ([Holm-Hadulla, 2011](#)).

Yet, neurobiological and psychological research as well as cultural studies show ubiquitous dialectical processes between construction and deconstruction, and order and chaos. More specifically, the dialectical interplay of crystalline and fluid intelligence, convergent and divergent thinking, and conscious and unconscious imagination plays a major role in the creative process. The description of creative persons by seemingly contradictory attributes coincides with a dynamic and performative conception of personality. Examples include the productive dialectical interplay of discipline and flexibility, and resilience and sensitivity that contributes to creative achievements.

The theoretical insight into the dialectics of creativity is of practical relevance, for instance, in the reciprocity of external stimulation and undisturbed autopoietic activity of the brain. The mind combines creative ideas within a domain that is periodically autonomous from sensory input. This is consistent with psychological findings and cultural studies that show that creative incubation and illumination need knowledge and skills on the one hand and undisturbed realms for free association and playing on the other.

Practically, the insight into the dialectic of coherence and incoherence, stabilization and destabilization, and satisfaction and frustration in the creative process may inspire a creative person to look for synthesis and flow but may also help to facilitate the acceptance of a certain amount of chaos and stress while creatively shaping one’s reality. The acknowledgment of the dialectics of personality traits that are associated with creativity may reinforce “creative bipolarity.” In all creative domains, one aspect of dialectical thinking becomes especially important: Dialectical thinking is a communicative process between past, present, and future in our social lifeworld.

The creative development of the dialectics of construction and destruction is the main task of humankind. One of the greatest advances in modern physics, the discovery of nuclear fission, led to the creation of the atomic bomb, which unfolded an unbelievable potential for destruction. The ecological destruction of the early 21st century is another example of the double face of human creativity. Furthermore, the media has brought free access to international knowledge with the innovation of the Internet, but also a variety of “creative” productions that contribute significantly to violence and (self-) destruction. The individual technologies and sciences by themselves cannot justify the reasonable application of their innovative results and products. A dialectical discourse ethic seems to be necessary to reasonably apply creative achievements in a global world of conflicting interests ([Habermas, 2011](#)).

Glossary

Effective surprise A part of how creativity can be defined. Creativity always involved originality, but it also requires some effectiveness, and the novelty of the creative idea often means that reactions to a creative idea, because the creative idea is indeed novel and yet effective, is surprise.

Formal effectiveness This is a second kind of effectiveness offered by Bruner. It is a matter of logic and mathematics, and occasionally music. Bruner quoted the mathematician Henri Poincare when discussing this: "creative thinking uses combinations that "reveal to us unsuspected kinships between... facts long known but wrongly believed to be strangers to one another" (p. 5).

Metaphorical effectiveness This is the third kind of effectiveness. It involves connecting domains of experience that were apart. The paradoxes that are often found in creative products may be a result of metaphorical effectiveness.

Novelty One requirement for creativity, though the concept is often labeled originality. They are, then, close to synonyms. At least one, originality or novelty, must be present for something to be creative.

Personal Creativity Creativity which does not depend on cultural or social input and may be original and effective only for the individual. Social recognition is not involved in personal creativity, though it may come later.

Predictive Effectiveness This is one of Jerome Bruner's distinctions in his work on the effectiveness that is required for creativity. This kind of effectiveness occurs when we look back and see the benefits of the creation.

Primary creativity A form of creativity that is largely unrelated to cultural or social inputs. It is personal but may eventually be shared, in which case it becomes social. Primary creativity is used by creators themselves and may be contrasted with secondary creativity which is the creativity of an audience.

Proactive Creativity Creative action that, unlike reactive creativity, need not be expressed. Proactive creativity may be seen in problem finding, which can be contrasted with problem solving.

Secondary Creativity The creativity of an audience when they construct meaning based on a new idea offered by a creator. They are in the audience and thus recipients but must be creative if they are to find meaning in the new idea. It is a different kind of creativity from that used by the creator him- or herself, but it is creative nonetheless.

Self Actualization The highest level of development. It involves spontaneity, self-acceptance, and creativity.

Standard Definition of Creativity A definition which points to two and only two requirements, namely originality and effectiveness. Each of these may be labeled in different ways. Originality may be novelty, for example, and effectiveness may be utility, fit, or relevance.

Utility A requirement for creativity, though not the only one. It is much like *effectiveness* but utility is consistent with the definition used by the United States Patent and Trademark Office (USPTO) which in turn has influenced several theories of creativity.

Introduction

This entry explores a topic that has received very little attention, but at the same time is very important. It explores how creativity is associated with dignity. This is an important topic because dignity is a part of what it means to be human and what it means to be fully alive. Dignity has been associated with high levels of functioning and high levels of maturity, as well. The world would be a better place if every human lived a dignified life.

To begin it is useful to examine the work of a scholar who contributed mightily to creativity studies, namely Jerome Bruner. He is especially well known for his idea about *effective surprise*. This is how he defined creativity—creative things have effective surprise. That idea adds a nice bit to the *standard definition* of creativity which points to originality and effectiveness. Effective surprise is

a good addition to the definition of creativity because very often, when a creative idea is shared with an audience, they are surprised even though the idea is effective. One well known example of this kind of surprise is that of Thomas Henry Huxley who, after first reading Charles Darwin's theory of evolution, claimed, "Why didn't I think of that?"

The advantages of including surprise in the definition of creativity have been detailed by several scholars, most notably Dean Keith Simonton. He drew heavily from the definitions and methods used by the US Patent Office, the rationale being that they had a procedure in place that allowed them to determine if a patent should in fact be awarded. Simonton slightly modified the terms of the USPO method and suggested that creativity be defined in term of *novelty*, *utility*, and *surprise*. The term utility is not far from effectiveness. Simonton explored four implications of this approach to creativity. These involve (1) expertise, (2) comparability, (3) the role of blind variation and selection retention, and (4) differences between objective and subjective evaluations. The last of these is relevant to the present discussion and will be explore below.

Varieties of Effectiveness and the Benefits of Creativity

Bruner's suggestion of adding effective surprise to the definition of creativity is frequently cited, but actually he said much more about effectiveness. The details he offered in this regard should be considered carefully because effectiveness is a broad term and surprisingly difficult to define in a way that applies well to creativity. This is why so many other terms are sometimes used along with or instead of effectiveness. Just above utility was used, but relevance, fit, appropriateness, and usefulness have also been used.

Thus is interesting that Bruner distinguished between several kinds of effectiveness:

Predictive effectiveness occurs when we look back and see the benefits of the creation.

Formal effectiveness is a matter of logic and mathematics, and occasionally in music. Bruner quoted [Poincare \(1913 p. 181\)](#) when discussing this: "creative thinking uses combinations that "reveal to us unsuspected kingships between... facts long known but wrongly believed to be strangers to one another".

Metaphorical effectiveness involves connecting domains of experience that were or appear to be apart (e.g., Santa Maria Alba, with a face showing her as "virgin, strumpet, flirt, daughter, wife, and mother all at the same time"). That example implies that many of the seemingly paradoxical creative products offered in history (e.g., the concept of complementarity) involved metaphorical effectiveness. There are a number of theories of creativity that point to the role of metaphorical thinking as well.

It will come as no surprise that when Bruner was exploring the various kinds of effectiveness that he also offered ideas about the benefits of creativity. After all, creative things are often beneficial when they are effective, or beneficial only because they are effective. The benefits of creativity are diverse and include.

Problem solving
Adaptability and flexibility
Psychological health
Physical health
Innovation
Invention
Learning & growth (across the lifespan!)

That is an impressive list, and it is even more impressive because each of the benefits listed is an umbrella concept. There are specific benefits subsumed under each.

This leads us to a benefit that is not listed above, nor mentioned when the benefits of creativity are itemized by others. Usually lists of benefits follow from the fact that creativity is a kind of effectiveness—it is effective surprise, or, more commonly, effectiveness combined with originality or novelty. Yet there are benefits that do not follow from the definition that includes effectiveness. I am referring to dignity.

Bruner (1962, p. 2) wrote,

There is good reason to inquire about creativity ... A reason beyond practicality ... The reason is the ancient search of the humanist for excellence ... the next creative act may bring [us] to a new dignity.

This may imply a kind of paradox, but paradoxes often play a role in the creative process. This is clear in reviews of ECCENTRICITY, HYPERSPACE, and the MAGIC SYNTHESIS, each of which is tied to creativity elsewhere in this volume. Paradox is also tied to creativity in some personality research ([McMullan, 1976](#); [Csikszentmihalyi, 1996](#)). Csikszentmihalyi, for example reported a large study of highly creative individuals and found many to be simultaneously feminine and masculine, introverted yet extraverted, mature and yet at other times childlike.

The paradox implied by Bruner's view involves the very practical benefits resulting from the effectiveness of creativity, but also less objective benefits of creativity, including dignity.

This is an enormously important point, in part because the objectively practical side of creativity seems to be taking over the field of creative studies. Businesses and advertisers are using creativity whenever possible, for example. Creativity is listed as one of the

most desired characteristics in the workforce (IBM, 2000) and is one of the top three skills predicted to be required in the job market in 2020 (World Economic Forum's [Future of Jobs Report, 2016](#)). Adidas has athletes bragging about their creativity ("create the game") in order to sell shoes, and creativity or something that depends on it is explicit in the advertisements of IBM, Hewlett Packard, Microsoft ("Everywhere, people are using the Microsoft Surface Pro 4 to unleash their creativity"), Nissan ("Innovation that excites"), and even Absolut Vodka ("Fueled by Creativity").

Bruner was not worried about this increased emphasis on what he called the pragmatic side of creativity. Indeed, he had an explanation for how the dignity that is possible with creativity has increased its importance rather than diminishing as its practical side has boomed. He put it this way:

In periods during which man saw himself in the image of God the creation of works *ad maiorem Dei gloriam* ["For the greater glory of God"] could provide a sufficient rationale for the dignity of the artist, the artisan, the creative [person] but in an age whose dominant value is a pragmatic one and whose massive achievement is an intricate technological order, *it is not sufficient to be merely useful* (italics added p. 2)

This takes us to one of several explanations of how creativity is related to dignity. Simply put, a person might be creative because it is practical, but sometimes in life it is not enough to be merely pragmatic. Practicality becomes fundamental, but it does not give meaning to life. To give meaning to life requires something more. Expressing creativity that is not motivated by practical needs may be that "something more."

In this light, creativity can be enormously useful, but that kind of creativity is not necessarily dignified. It is instead a response to a need and often rewarded. This expression creativity might be a solution to a problem, so the creativity is a kind of problem solving. But creativity is not always problem solving. There is problem solving that is uncreative, and creativity may involve self-expression, problem finding, or dignity and thus not be problem solving. You might say that dignified creativity is not a means to an end; but care must be taken. It may be that creativity leads to a personal ends or solves a personal problem. In this light dignified creativity may be a part of PERSONAL CREATIVITY [elsewhere in this volume] and not a social endeavor. That would mean that dignified creativity is practical, but perhaps practical for the individual alone and not in any socially-recognized fashion.

The labels objective creativity and subjective creativity, first proposed by Stein (1953) and later used by Beghetto and Runco (2019), might be used to distinguish between creativity which is effective in the sense that others can see (objective) vs. the creativity that is only personally meaningful (subjective). This is not a hard-and-fast distinction, however, which was why Beghetto and Runco used primary and secondary creativity instead. They described how the latter might actually include both subjective and objective processes.

Shared Dispositions to Be Creative

There are other ways in which creativity can be dignified. To explain, consider the fact that creativity is a reflection of a genetic disposition which is shared by all humans. Yet not everyone uses their creativity. Why not? One reason is social: society prefers conventions and conformity. There is pressure to get along. Another reason is economic, but not in a financial sense, or at least not always. The term economic here is used as a label for the science of resources. Simply put, creativity requires expending resources. People may invest in their creativity (e.g., temporal investments where they develop expertise or work on some original project) and may not invest in other things (e.g., conventional skills) because they are focused on creativity. Everyone could be creative, and most people probably are, once in a while, but for most people the creativity is practical. What of the creativity that is simply an expression of one's potentials? This would be dignified. We all have an inborn capacity. To use it when there is no pragmatic reason and to use it so it does not go to waste can be dignified. It may be that this is what Bruner meant when he wrote, "The artist, the writer, and, to a new degree, the scientist seek an answer in the nature of their acts. They create or seek to create, and this in itself endows the process with dignity ... (p. 2) It may be that Gruber (1993) was also suggesting something like this in his article titled, "Ought implies can implies create." Then again, he was clearly looking at creativity as a "moral imperative," and here creativity is more of a personal, developmental imperative.

The idea that putting effort into fulfilling one's potentials, even when there is no pragmatic reason to do so—and in fact there may be social pressure to conform instead—suggests that the concept of dignified creativity fits with the theory of creativity that emphasizes authenticity. Maslow's (1973) humanistic approach to creativity includes authenticity. He tied authenticity to self-actualization and the fulfillment of potentials. As a matter of fact he eventually concluded that self-actualization, which is the highest level of human development, is inextricable from creativity. I might add that dignity is similarly a reflection of a kind of maturity, in which case there is a syndrome or cluster of related tendencies found among mature individuals, authenticity, dignity, and creativity included. Critically, the word "maturity" used here should not be equated with age. In fact it may be that MacKinnon's (1960) description is more accurate. He described creative individuals in his article on "the highly effective person." Given that this entry started with a review of the bridge between effectiveness and the practical possibilities of creativity, it seems that maturity would avoid confusion that the label effective might create.

The Human Condition

There is yet another way in which creativity can be dignified. Think back to the distinction between problem solving and problem finding used briefly above. The former tends to be reactive. The latter is likely to be proactive rather than reactive. Why might a person be proactive? By definition he or she need not emit the behavior; the behavior is not elicited or required. So why display it? Perhaps because it is the right thing to do, which is not far from what Gruber (1993) meant. His focus was on morality, however, and there is another way to look at this which may not be clearly tied to morals. I am referring to the fact that a person might be proactive because it is the right thing to do, and not because of shared morality but just because of the human condition. People might be mindful, even though they could be mindless instead (Langer, 1989). People need not invest in their own potentials, but they sometimes do—just because those potentials exist. People might just go through life reacting to what is imposed, but they do not need to live this way. They can instead make choices, do things that need not be done but can be done—including working to fulfill one's own potentials. Recall here that we all have the potential to be creative, and it is dignified to fulfill that potential, to behave proactively, to make choices that need not be made, but can, including the choice to live a creative life. For some, this is what brings meaning to life.

Thus, dignity is possible when we create meaning. Or perhaps just because we create, period. We invest in the process of living and we bring something to the Person X Experience transaction so often described in psychology. We are not passive recipients. We do not waste the human potential to create.

What Is Discovery?

Discoveries are unexpected surprises that alter how we understand nature and the ways we go about studying it (Kuhn, 1957). Sometimes discoveries result from changes in perspective, so that for Noble laureate Albert Szent-Gyorgyi, "Discovery is seeing what everyone else has seen and thinking what no one else has thought." (Szent-Gyorgyi, 1963, p. 48) Even in the discovery of new phenomena, there is always a concomitant intellectual or theoretical leap. At least a dozen people saw the fogging of photographic plates by radioactive materials before William Roentgen recognized that it was not a problem with the manufacture of the plates, but of something in the laboratory causing the fogging. The search for that cause led to the discovery of x-rays. More than two dozen bacteriologists saw antagonisms between microbes before Alexander Fleming thought to try to isolate the first antibiotics. Even the discovery of a new species of plant compound or star is only interesting or important within the context of broader issues of chemical engineering, pharmacology, taxonomy, evolution, or cosmology. Martin Harwit argued that, "the distinction between mere detection and actual recognition of a new phenomenon is therefore crucial. We may now be detecting many phenomena that we do not recognize." (Harwit, 1981, p. 31) Discovery requires both recognition and interpretation. However, part of this process involves social forces that determine the dominant paradigm and control the latest fads in funding and hiring, and even aesthetic considerations (Edge and Mulkay, 1976). These factors can aid or slow acceptance of discoveries. In sum, the surprise of insight that some investigators identify with discovery is but one temporally distinct phase within a complex process of reshaping our understanding of natural phenomena and the means for investigating them.

Who Discovers

Every discovery to date has been made by a person. In the age of computers, this is not a trivial statement. So far, several computer programs have generated novel proofs of previous conjectures made by human beings, but no computer has yet generated a new and useful problem, hypothesis, or conjecture, let alone observation. As Poincaré once said, logic proves, it does not invent. Whether computers will be able to be programmed to have "imagination" in the future will stand as one of the greatest challenges of artificial intelligence, manifested by a program capable of inventing something novel that it was not programmed to do (the so-called "Lovelace test").

Given that people have made all known discoveries up to the present time, one must ask what characterizes discoverers. Scientific talent appears to be just as asymmetrically distributed in the general population as is, say, musical or artistic talent. While nearly everyone can learn to do an experiment or play an instrument, few have the talent of an Einstein or a Mozart. Recognizing this talent is not a trivial problem. Einstein's potential was certainly overlooked well into his adult years; Darwin displayed no obvious talent for science as a young man; Mendel's work was completely ignored during his lifetime. A few eminent scientists have, however, displayed the same sort of precocity as Mozart. William Bragg, who won the Nobel Prize at the age of 22 is one example. Notably, studies of precocity among scientists, as determined by high standing in Science Talent Search competitions for high school students, shows that while some national winners have gone on to win Nobel prizes, most precocious teenagers do not even go on to pursue science careers (Subotnik et al., 2001). Achievement tests, tests of divergent thinking, and psychological profiles have also failed to identify any significant predictors of who will succeed in science (Root-Bernstein et al., 1993). Some eminent

scientists (e.g., Nobel laureates Harold Varmus and Hans von Euler-Chelpin) moved into science careers only during or after college, making their talents relatively late blooming.

Factors correlating with eminence in science are of unexpected sorts. One is training with a previously successful discoverer. Nearly all Nobel prize winners have studied with a previous laureate at some time during their schooling or early careers suggesting either that talent recognizes talent, or that some of the “tricks of the trade” can be learned by apprenticeship.

Discoverers are also often highly talented in their avocations, so that a significant proportion of Nobel laureates report that they have faced difficult career decisions between science, one of the arts, and sometimes the law or business as well. A few, such as Desmond Morris, who is a professional painter as well as ethologist, and Aleksandr Borodin, whose musical compositions are better known than his chemistry, managed to carry on joint careers. Whether the correlation between avocational ability and professional eminence is a result of talented scientists being generally talented or a result of avocational skills priming scientific creativity is currently an unresolved issue, but the majority of polymathic scientists state that arts and crafts avocations have identifiable utility for their scientific work (Root-Bernstein et al., 2019). As Nobel laureate Max Planck said in the introduction to his autobiography, “the creative scientists needs an *artistic* imagination” (see Avocations and Polymaths).

Age is also a factor in making discoveries. Young scientists are more likely to make discoveries than older ones and the earlier that a scientist begins independent research, and the earlier she publishes, the greater her probability of long-term recognition. The probability distribution of making a discovery varies by specific discipline, however. The probability peaks at around 25 years of age for mathematicians, 30 for physicists, 35 for chemists, and in the early forties for biologists. As with all statistical distributions, there are, in this case many important exceptions.

Few scientists make even one notable discovery during their careers while a small minority are continuously productive of high-impact research over many decades. The former tend to stay within the field in which they were trained; the latter change fields regularly (Root-Bernstein et al., 1993). Productivity does not predict impact, some of the highest impact scientists, such as Gregor Mendel and Frederick Banting having produced only a few papers. Conversely, some of the most important scientists and inventors produced hundreds of papers or patents, but only a handful have had significant impact. Quality of discoveries or inventions made by an individual is of much greater consequence than the quantity.

A significant number of discoveries have been made by amateurs (see Art/Science, this volume). Amateur astronomers have been responsible for the first sightings of the planet Pluto and of many of the comets that have been named. The farmer Wilson Bentley, known to posterity as “the snowflake man,” provided some of the best data and many of the key concepts in meteorology. And it is worth remembering that Charles Darwin, Mary Leakey, Jane Goodall, Dian Fossey, and many other eminent biologists were amateurs who learned their craft by doing it.

How Discoveries Are Made

Discoveries come about in as many ways as there are discoverers. There are, however, some general strategies that seem to work more often than others (Root-Bernstein, 1989, pp. 407ff). Peter Medawar (1979), a Nobel laureate in Biology, admonished students that if they want to make an important discovery, they must choose a big, important problem. G. P. Thomson, a Nobelist in Physics, noted that there is no correlation between difficulty and importance of a problem. The big ones can be just as easy (or difficult) to solve as the little ones. Neils Bohr, another Physics laureate suggested that the best problems can be found by focusing on paradoxes – the places where theories and observations are non-congruent or contradictory. Nobel Prizewinner Linus Pauling argued that the key to success is to, “have lots of ideas and throw away the bad ones.” To succeed in science, you must dare; and to dare, you must be willing to fail.

Error itself is a frequent source of discoveries. Every discoverer of note has made errors from Newton and Vesalius to Einstein, Crick and Watson. What distinguishes the discoverer from the forgotten scientist is that the discoverer usually recognizes in his own errors the seeds of new possibilities. Thus, Karl Popper maintained that hypotheses and theories can only be disproven, but never verified, so that all progress comes from identifying where our knowledge fails. Instead of searching for data to confirm preconceived hypothesis, scientists should instead search for data that can *disprove* their hypothesis.

However, not all philosophers of science or working scientists believe that it is any more possible to disprove hypotheses than to prove them. Thus, many scientists advocate some version of Chamberlin’s “method of multiple working hypotheses” (Elliot, 2007). Chamberlin argued that existing data should be used to generate as many plausible explanations as possible and the differences between these explanations subjected to comparative tests. Scientists utilizing this method are very explicit that the “winner” of this competition is not necessarily “right”, but merely the best explanation of available evidence.

The recognition of anomalies is another fecund source of discoveries (Kuhn, 1962). Anomalies are data that contradict theoretical expectation. Sometimes anomalies indicate the limitations of the theory; sometimes they point to a phenomenon that has previously been missed. For example, the discovery of the element argon resulted from the observation that nitrogen prepared from the air is heavier volume for volume than that prepared from chemical compounds. Lord Rayleigh discovered that atmospheric nitrogen is “contaminated” with an unsuspected element called argon, which, because it is non-reactive, accumulates in air but is not found in chemical compounds.

Another common strategy is to extrapolate. As soon as Rayleigh announced the discovery of argon, William Ramsay predicted from Mendeleev’s periodic table of elements that there should be an entire column of previously unsuspected inert gases in addition to argon. He proceeded to isolate them. Rayleigh and Ramsay both won Nobel Prizes for their work.

Other scientists played mental games with current scientific dogmas, turning them on their heads, contradicting basic premises, or simply wondering “what if” some principle that everyone considered to be unquestionable were not. Analogies, metaphors, and even the re-creation of ancient historical experiments have all been touted as additional aids to discovery (Root-Bernstein, 1989) (see Analogies and Metaphors).

In conjunction with strategies of research, many scientists and inventors described using an unusual mental “toolkit” in making their discoveries. Strikingly, very few eminent scientists claim to use either mathematics or verbal languages to do their creative thinking. Einstein, in fact, stated explicitly (in what may amount to an over-statement) that, “No scientist thinks in equations” (Root-Bernstein and Root-Bernstein, 1999). He explained to his colleague Jacques Hadamard that in his case, he did his problem solving by using “certain signs and more or less clear images which can be ‘voluntarily’ reproduced and combined ... as well as muscular feelings ...” (Root-Bernstein and Root-Bernstein, 1999). Einstein also noted that the use of words and equations came only when the images and feelings had become well enough developed that they needed to be formally tested and communicated. Cyril Stanley Smith (1981), a metallurgist, similarly noted that “The stage of discovery was entirely sensual and mathematics was only necessary to be able to communicate with other people.” The use of visual images, kinesthetic feelings, and other non-verbal forms of thinking, as well translating insights into words and mathematics only in a secondary stage of developing ideas, is a very common (Root-Bernstein and Root-Bernstein, 1999) (see Imagery).

This non-verbal, non-mathematical nature of creative thought creates some interesting conundrums for understanding the nature of discovery. What is Stan Ulam talking about when he claims to “calculate, not by numbers and symbols, but by almost tactile feelings combined with reasoning” (Ulam, 1976, 17, 147)? To what was Richard Feynman referring when he talked about solving quantum physics problems using “acoustical images” (Root-Bernstein et al., 1995)? How do objective and verifiable results come from a process of thinking that has been described as entirely sensual, empathic, and subjective? Here, physicist-novelist C. P. Snow may hold the key:

If we could follow the process of scientific thought through many minds, as it actually happens and not as it is conventionally expressed after the event, we should see every conceivable variety of mental texture There are exactly as many ways of approaching the scientific world as there are individuals in science. It is only because the results are expressed in the same language, are subject to the same control, that science seems more uniform, than, say, original literature. In effect, in the end, it is more uniform.

Snow (1934, 258–260)

Unless the idiosyncratic and non-logical nature of thinking itself is recognized and the immense constraints that logical systems of communication place on how insights are expressed, there cannot be progress on this thorny problem. There is clearly a process of translation between individual and the scientific collective that is as essential to success as having the insight itself (Root-Bernstein and Root-Bernstein, 1999).

When Discoveries Are Made

Temporal patterns of discovery are perhaps the least-studied aspect of the discovery process, but some interesting phenomena have been observed. People tend to make discoveries within five to ten years of entering a field, and they tend to have only one major insight per field they enter. Thus, changing fields tends to restart the discovery clock, as it were – a phenomenon that has been called “the novice effect” (Root-Bernstein, 1989, p. 419).

Insights seem to occur more often when scientists are *not* directly working on a problem than when they are. Several studies have shown that only about a third of scientific problems are solved by a direct, brute force approach (Root-Bernstein et al., 1993). An equal number are solved when scientists give up on the original problem and begin working on a related problem. The remaining third of the problems get solved during leisure-time activities, which range from going on vacation to taking a shower to dreaming the answer in one’s sleep.

Discoveries tend to occur during times of economic growth and cultural mixing. The Scientific Revolution, for example, occurred during a period of prosperity associated with the Renaissance and this historical period is also characterized by many voyages of discovery that led to trade – both economic and intellectual – between cultures as diverse as the Europeans, Arabs, Chinese and Native Americans. Other major periods of innovation in the sciences, such as the Industrial Revolution and the post-Sputnik era, are also associated with such economic and cultural prosperity. One reason for this is that new technologies drive scientific advances. Harwit (1981) documented immediate and rapid innovation and discovery following the introduction of a novel technology into a scientific field, followed by an equally rapid drying up of novel results.

What Is Discovered

Much of the literature on discovery assumes that what is discovered is a solution to a problem. Thus, one popular book by Horace Judson about discovery is actually entitled *The Search for Solutions*. In fact, discovery is better characterized as a quest for questions (Root-Bernstein, 1989). The problem must be discovered before the search for its solution begins.

The greatest scientists often excelled at discovering new problems. Thus, Einstein once wrote:

The formulation of a problem is often more essential than its solution, which may be merely a matter of mathematical or experimental skill. To raise new questions, new possibilities, to regard old problems from a new angle, requires creative imagination and works real advance in science.

Einstein and Infeld (1938, 92).

Being able to perceive problems where no one else sees them is therefore one critical skill a discoverer can cultivate (see Problem Finding).

Outstanding problems are often as widely disseminated and discussed by scientists as are great experiments and theories. James Watson and Francis Crick, for example, tackled the well-defined problem of how genetic information is encoded and transmitted by living organisms. They neither discovered the problem nor the fact that DNA (deoxyribonucleic acid) carries genetic information. They did, however, make the very remarkable discovery of how the structure of DNA itself carries information and is adapted to replicating itself. This structure was quite unexpected (Watson, 1968).

All scientific discoveries are interwoven. Watson and Crick's discovery was only made possible by other types of discoveries. W. H. and W. L. Bragg had previously invented the technique of x-ray crystallography by which the structure of DNA was analyzed; Linus Pauling had developed sophisticated physicochemical modeling methods that Watson and Crick could apply to DNA; and so forth. In turn, Watson and Crick's discovery led to other discoveries. All of modern genetic engineering is based on the manipulation of DNA sequences and the enzymes that control DNA in cells – not one of which was foreseen even at the time of Watson and Crick's work (ca. 1950). Thus, it is correct to say that every discovery builds upon prior discoveries and, if it is valuable, makes new ones possible.

Where Discoveries Are Made

Where scientific discoveries are made is another under-studied aspect of the subject, and one that is full of surprises. One might expect discoveries to cluster in the major centers of science at any given historical period since these centers are where the most prominent scientists are to be found. For various reasons indicated above, including the inverse correlation between age and discovery and the generally conservative tendencies of most major institutions, the most interesting science is usually done in peripheral institutions.

Before proceeding further with this point, it is first important to distinguish between what Tomas Kuhn (1962) characterized as “normal” and “revolutionary” science. Kuhn defined normal science as having a well-articulated paradigm, or set of problems and problem-solving techniques, that can be described in textbooks and classrooms and implemented in laboratories. Normal science focuses on areas of science in which a major advance has opened up a well-defined set of problems that can be addressed with a fair assurance of success. Revolutionary science, on the other hand, is science that overtly challenges the assumptions of existing paradigms, undermining textbooks, making standard classes irrelevant or outmoded, and creating new methods of working and training. Since Kuhn, historians of science have begun to recognize a third category of science as well: new sciences. There was, for example, no science of physical chemistry until the late 19th century when scientists began to realize that the techniques of physics could be applied to chemistry. Physiology, immunology, molecular biology, biophysics, astrophysics, and ethology are other examples of new sciences that emerged during the last century, carving out new scientific territories without attacking existing sets of theories, practitioners, institutions, or textbooks.

Each type of science has its own geographical distribution. Normal science, does indeed cluster in established centers of science (Root-Bernstein, 1989). These centers have the resources and funding to attract recognized discoverers. These recognized centers are the places where the highest level of normal science is being carried out.

Breakthrough or revolutionary science tends towards the geographical peripheries of the scientific collective at any given time (Root-Bernstein, 1989; Root-Bernstein and Pawelec, 2016). There is a socio-economic price to be paid in challenging paradigms, so that, as one scientist put, one makes a choice between the “shackles of the palace or the freedom of the shack.” Many revolutionary scientists (Einstein is a well-known example) therefore spend their early careers unemployed or marginalized into peripheral institutions such as patent offices. One factor in this marginalization is that successful scientists often resist scientific innovations, sometimes even forcing innovators out. Hans Gaffron called this “resistance to knowledge” and it is a well-characterized phenomenon in the sciences.

New sciences also tend to emerge on the geographical peripheries of science (Root-Bernstein, 1989). Two sets of institutions tend to take up new scientific fields: major institutions that purposefully restructure existing departments to create a new one to embody the new science and its discoveries; and, more frequently, new institutions. For example, the new science of physical chemistry found its first homes prior to 1900 in the just-founded University of Amsterdam and at other virtually unknown colleges and universities in Tartu (Latvia), Toulouse and Bordeaux (France), Liverpool, Dundee and Aberdeen (UK), and Yale University in the United States (which was notable for its lack of scientific faculty at the time). Discoveries, in other words, tend to flourish where new opportunities for personal and institutional growth are available and there is lack of competition with established centers of practice.

Where one trains as an undergraduate has, notably, little or no effect on one's chances of getting into the National Academy of Sciences, the Royal Society or winning a Nobel prize, but where a scientist does their doctoral or post-doctoral training is critical (Root-Bernstein and Pawelec, 2016), perhaps because of the phenomenon mentioned above that most eminent scientists study with eminent mentors (see Mentors).

Why Discoveries Are Made

What motivates scientists to make discoveries? The basic drives seem to be control, curiosity, necessity, serendipity, and aesthetics. Often several of these drives are at work simultaneously.

Einstein commented that one of the primary reasons he became a scientist was to avoid the daily hassles of life. Many studies of the psychology of scientists and engineers suggest that they have a need for control. Creating theories or performing experiments provides that control. Control, in turn, yields power, since understanding nature allows human beings to manipulate nature's laws. Thus, discovery provides a means for individuals to obtain power over nature and their own circumstances.

Necessity can also be a motive for discovery. "Necessity is the mother of invention" is a well-known saying, no less true for its triteness. It is certain that many scientists, such as Louis Pasteur and Jonas Salk, have tackled questions of the cause of diseases precisely because of the threat these diseases posed to human beings.

At least half of all discoveries occur serendipitously, however (Root-Bernstein, 1989). A careful distinction must be made here between serendipity and chance or accident (Meyers, 2007). Chance and accident denote total lack of control of the process leading to discovery. No discovery has ever been made by chance or accident, despite many articles and books on these topics. When the laboratory notebooks detailing discoveries are examined, they inevitably reveal that all discoveries begin with some goal in mind. Those discoveries that are often said to have occurred by chance or accident turn out to have been made while looking for something else. Finding one thing while searching for something else is the definition of serendipity. Thus, Fleming, for example, discovered the antibiotic enzyme lysozyme in his mucus and tears when trying to isolate a virus that causes colds. Intention set up the experiments; serendipity yielded the surprising discovery.

Perhaps the most unexpected and yet common motivation for discovery is aesthetic (Wechsler, 1988; McAllister, 1996). A very large number of scientists are drawn to science in the first place by the beauty of the experimental preparations they examine in the microscope or the sublimity of the intellectual constructs that we call theories. Santiago Ramon y Cajal, who won a Nobel prize for his work in neuroanatomy often waxed eloquent over the magnificent scenes that the architecture of the brain afforded, while Max Planck said forthrightly that he was drawn to physics by the beauty of the laws of thermodynamics. In some cases, the desire to recreate literal physical beauty has even led to discoveries. For example, C. T. R. Wilson became so enamored of the coronas and glories that he observed when climbing in the Scottish hills that he decided to recreate them in his physics laboratory. His success inventing cloud chambers not only allowed him to make these beautiful optical phenomena at will, they also allowed subatomic particles to be observed for the first time, and earned Wilson a Nobel prize. Similarly, it appears that Fleming's habit of making "paintings" in petri dishes using a "palette" of colored microorganisms provided the basic techniques and observations that led to his discovery of penicillin.

Multiple or Simultaneous Discoveries

Many discoveries are made simultaneously by two or as many as a dozen other people or groups of people suggesting that common problems lead to common solutions. Discoveries that are made independently by more than one individual or groups of individuals are termed "multiple" or "simultaneous" discoveries (Kuhn, 1957). The probability of simultaneous discovery is hinted at by the fact that many other scientists saw what Fleming and Roentgen saw without thinking it. Sometimes, if a problem is well enough defined and the techniques for investigating it are available to enough people, several will converge on the same general answer at the same time. The simultaneous discovery phenomenon brings into contrast the extent to which discovery is dependent on unique forms of individual creativity and the degree to which there is a logic to discovery that is independent of individual psychology. The existence of simultaneous discoveries is also a prerequisite for understanding the controversies over priority that frequently occur in science.

The phenomenon of multiple discovery has been well documented in several cases. One is the invention of calculus by Newton and Leibniz at the end of the 17th century. Similarly, in the 1840s, Robert Julius von Mayer, James Prescott Joule, Ludwig A. Colding, William Robert Grove, and Hermann von Helmholtz (among others), all published versions of what would eventually become known as the first law of thermodynamics (energy is conserved). Numerous priority disputes broke out among the claimants. The co-publication of the theory of evolution by natural selection by Charles Darwin and Alfred Russell Wallace in 1858 is one of the few cases in which a simultaneous discovery did not result in friction between the co-discoverers, mainly because Darwin gave Wallace credit for his contribution and they co-wrote their first publication together.

Each example described above showcases the differences that always exist in the formulations of discoveries. Newton and Leibniz utilized very different, largely incommensurable notations. Darwin's formulation of natural selection was far more developed and encompassed a much wider range of phenomena than did Wallace's. Each of the formulations of the first law of thermodynamics has many more differences than it has similarities, and that it is only in retrospect, and largely due to the work of Helmholtz,

that one can recognize that all are partial statements of the same basic principle. Simultaneous discovery does not, therefore, necessarily, or even frequently, denote *identity* of discovery. Every investigator has a unique style of research that is manifested in how they pose problems, what tools they use to solve them, and how they present their findings.

What studies of simultaneous discovery tell us is that science-in-the-making is much more similar to art-in-the-making than might first appear. Style matters. Even when several scientists or groups of scientists make a common discovery, they imprint their unique personal and psychological factors onto that discovery so that no formulation is exactly like any other.

An Evolutionary Theory of Discovery

Evolutionary theory provides a unifying concept for understanding the process of discovery in all its manifestations. Kuhn (1962), for example, argued that an evolutionary model could be applied to science in his classic *Structure of Scientific Revolutions* and the argument has been elaborated since by Donald Campbell, David Hull, and the author (Root-Bernstein, 1989) among others.

In order to apply evolutionary theory to discovery, one must make analogies between species and ideas. Standard Darwinian evolution requires four key elements: 1) a source of diversity among species or ideas; 2) a way for individuals to inherit differences; 3) over-production of individuals so that not all can survive; and 4) a non-random means of selecting between differences. The sources of diversity are provided in part by nature, which generates the phenomena for scientists to observe, and in part by scientists, who invent techniques for exploring nature and explaining it. In practice, Chamberlin's method of multiple working hypotheses is always at work, often within the minds of individual scientists and certainly when the entire population of scientists is examined. At any given time in any area of active research, there is always a diversity of ideas and techniques being used or developed to explore the anomalous and unknown aspects of nature. Because individual scientists are trained at different institutions (recall the central-peripheral distinction made above) they integrate different sets of knowledge and techniques into their thinking and work resulting in a diversity of possible ways to know and explain nature.

The inheritance of variations occurs by means of learning and teaching in cultural evolution. Thus, ideas and information (sometimes called "memes") take the place of genes. Evolution, in consequence, is more Lamarckian than Darwinian. Lamarck maintained that species evolve by willing themselves to change and argued that alterations during their lifetimes could be transmitted genetically. Lamarck's mechanism has been completely dismissed as a means of biological evolution but may still apply to cultural evolution since people can, in fact, change their minds and transmit their altered ideas to the next generation of scientists. Unlike genetic evolution, learning is acquired and filtered by experience, expectation, and belief systems.

The third factor necessary for an evolutionary system is over-production of the diversity of inherited traits. If every scientific observation and every scientific hypothesis were considered to be equally valuable and valid, then there could be no progress. Scientists compete for grants, resources, students, publications, positions, prestige. Some are more fecund than others, passing on their ideas and techniques more efficiently than others. Only some can "survive" to become contributors to the scientific enterprise.

Finally, evolution requires a non-random means of selecting between competing ideas, methods, observations and experimental results. Here a combination of natural and artificial processes come into play. The touchstone of all science is nature itself. The scientist presumably compares observations and theories by means of tests with nature. Often, however, several explanations may account for existing observations equally well. In this case, other criteria, such as the compatibility of the various explanations with other scientific principles, the range of phenomena explained, its simplicity and usefulness, and aesthetic criteria come into play. Unfortunately, from a purist perspective, scientific ideas and results are also subject to social norms and expectations, transient fads, and political and economic factors. Such constraints may be as important as scientific considerations in determining which discoveries thrive or even survive at any given point in history or in any given society. The point is that selection does occur and competition amongst scientists, their observations, and theories is very rigorous if not always constrained to scientific considerations.

In sum, the discovery process fits a Lamarckian form of evolution. Evolutionary theory also accurately describes other elements of the discovery process. One is the literal growth of each new development in science from previous discoveries. Every discovery builds on previous discoveries. If necessity is the mother of invention, then existing discoveries are the fathers. One of the explicit "rules" by which most scientists abide is that new theories and discoveries must incorporate the existing body of scientific knowledge and understanding. Continuity with the knowledge and understanding accumulated in the past is a requirement for ongoing progress. There can be no clean breaks, even in revolutionary science, with what has already been established – only in how everything that is known can be more coherently and consistently explained.

An evolutionary model also describes accurately the increasingly specialized nature of discoveries in science. If one looks at science since the 17th century, it has developed in almost perfect imitation of a taxonomic tree. As of 1670, there was one journal of science, and all of science was generally categorized under the heading "natural history". Over the next century, the number of practitioners grew exponentially, as Derek de Solla Price so well documented in his classic *Little Science, Big Science*, creating a need for new and more specialized journals. The specific sciences of astronomy, physics, chemistry, and biology were all recognized by the end of the 18th century. During the nineteenth, exponential growth in the number of chairs of science, journals, practitioners, and papers all continued resulting in further specialization. Chemistry split into physical, organic, inorganic and biochemistry, for example. At present, the discipline recognizes over a hundred specialties in which doctorates can be obtained and papers published. Every scientific field has branched into similarly diverse specialties. From the trunk of natural philosophy have emerged the general branches of the basic sciences, followed inexorably by the twigs that have produced the

current crop of thousands of leaves that represent the crown of science as it exists today. Scientists diverge and specialize just as do species.

Many aspects of the evolutionary theory of discovery remain unresolved, however. For example, standard evolutionary theory places primary emphasis on the random generation of extremely large numbers of variants from which the best adapted can be selected. The implications of this approach for discovering are that an investigator should try as many random ideas or processes as possible in order to optimize his or her chances of making a discovery. Physicist [Henri Poincaré \(1946\)](#) placed the greatest emphasis on the selection process. Anyone can, he argues, find two ideas, theorems, facts, or techniques that have not been synthesized before and attempt to synthesize them. Most of the results will be useless or trivial. Poincaré therefore argues that what is most important is having an aesthetic sensibility that allows the discoverer to sort the wheat from the chaff: “To invent is to choose.” ([Poincaré, 1946](#)).

Another equally important difference between standard models of biological evolution and models characterizing cultures such as science concerns integration. Standard Darwinian evolution is portrayed as a tree that constantly branches. The most adapted new variants are the ones that survive through time. But much of scientific progress is characterized by the integration of previously separate lines of investigation, searching for “unified field theories” or their equivalents. Thus, the trees that represent scientific discoveries not only branch, but they also meld back together, forming a dense network of interactions. Symbiosis or synthesis yielding new sciences and more integrated theories is as important as speciation or specialization.

Innovation Versus Creativity

It is beguiling how the terms “innovation” and “creativity” are being used by different social actors including managers, educators, engineers, policymakers, and even leaders of countries. In a recent speech, Emmanuel Macron, the President of the French Republic, asserted that “the goal of making us stronger, restoring our ability to innovate, to produce, to reduce unemployment, particularly among the youngest people.” Theresa May, the former Prime Minister of the United Kingdom, declared, “I want us to be a secure, prosperous, tolerant country—a magnet for international talent and a home to the pioneers and innovators who will shape the world ahead.” And Barack Obama, the former President of the United States, mentioned, “Our single greatest asset is the innovation and the ingenuity and creativity of the American people ... It is essential to our prosperity and it will only become more so in this century.” Indeed, there are more examples of leaders who have acknowledged the significance of creativity and innovation as valuable human resources. However, where do these concepts overlap and where are they separate?

One of the greatest insights of Jean Piaget is expressed by his metaphor “To Understand is to Invent.” Misunderstanding the similarities and differences between innovation and creativity can cause confusion. One commonality between innovation and creativity is that both refer to ideas and products that are both novel and useful. In fact, few researchers explicitly distinguished between these two terms (e.g., Amabile and Pratt, 2017 ; Runco, 2014). Amabile and Pratt (2017) stated, “creativity, which we define as the production of novel and useful ideas by an individual or small group of individuals working together, is often conceived as the ‘fuzzy front end’ of innovation, which we define as the successful implementation of creative ideas within an organization” (p. 158). This definition suggests that creativity is a prerequisite for innovation; without creativity there is no innovation. Second, although both require some degree of novelty and utility, they differ in the novelty-utility ratio (Runco, 2014). Innovation requires new ideas with the main emphasis on utility, whereas creativity requires more originality or novelty. As Runco (2014) put it,

Innovation often requires that the result is maximally effective (it should sell or be publicly useful). Originality is secondary, though necessary. In creative performances that are not innovative, such as arts, originality may be much more important, whereas effectiveness is secondary. (p. 398)

School children might figure out a creative solution for a particular problem; however, they find it difficult to implement their ideas because of a lack of resources and/or knowledge. This takes us to usage. Creativity is used in educational contexts, while innovation is extensively used in organizations. This makes sense because companies and organizations focus on the effectiveness of innovative products and processes.

The final difference concerns motivation source. Creative individuals are driven by their intrinsic motivation to solve a problem, generate ideas, or create artistic expressions; whereas, innovation is mostly driven by extrinsic motivation (that is, making a profit). In business, for example, managers and investors care more about the implementation of creative ideas, that is, how much money a product will bring to the company. Recently more interest has been shown in innovation in non-profits where utilizing funds efficiently and effectively is crucial to the success of organizations. In summary, although innovation and creativity might overlap with each other, these two terms are not synonymous. The focus of this entry is on innovation, and more specifically, disruptive innovation.

What Is Disruptive Innovation?

Disruptive innovation has been scrutinized by researchers from various academic disciplines including economics, education, and medicine. Perhaps the term itself is catchy, or maybe the theory of disruptive innovation is very appealing and convincing. Although

the theory of disruptive innovation was introduced first in 1995 by Clayton Christensen and colleagues, the idea of market “disruption” was studied by the Austrian politician and economist, Joseph Schumpeter in the 1940s. In his book, *Capitalism, Socialism and Democracy*, Schumpeter inaugurated the idea of creative destruction, which he defined as “a process that revolutionizes the economic structure from within, incessantly destroying the old one, incessantly creating a new one” (Schumpeter, 1942, p. 83). The question is what are the factors contributing to selective market destruction? Through observing cases in which successful firms—with capital, capable employees, and expert leadership—were “disrupted” by entrants who had less resources, Christensen and his colleagues introduced the theory of disruptive innovation, which has since been extensively researched.

Christensen and his team elaborated on the theory of disruptive innovation through different articles and books such as *The Innovator's Dilemma*, *The Innovator's Solution*, and *Disrupting Class*. Christensen et al. (2017), defined disruptive innovation as:

A process whereby a smaller company with fewer resources is able to successfully challenge established incumbent business. Specifically, as incumbents focus on improving their products and services for their most demanding (and usually most profitable) customers, they exceed the needs of some segments and ignore the needs of others. Entrants that prove disruptive begin by successfully targeting those overlooked segments, gaining a foothold by delivering more-suitable functionality—frequently at a lower price. Incumbents, chasing higher profitability in more-demanding segments, tend not to respond vigorously. When mainstream customers start adopting the entrants' offerings in volume, disruption has occurred (p. 31).

According to this definition, disruptive innovation occurs as a result of an established incumbent's focus on customer needs and on research and development. As a consequence, established firms overshoot the market by presenting products that exceed the needs of customers. This definition also suggests that although the incumbents have the adequate resources to respond to the disruptive innovation; they ignore that disruption. By doing so, established firms open the door for those ignored entrants to dominate the market.

New entrants start by targeting customers who cannot afford to buy a product or a service because it is too expensive and/or exceeds their needs. Entrants, therefore, offer convenient, simpler, and cheaper products or services that satisfy those needs. With time, entrants develop their products to attract mainstream customers who are willing to pay less for a product or service that meets their needs (see Fig. 1; Christensen et al., 2015, p. 49).

In order to support their theory, Christensen and colleagues provided more than 70 examples of disruptive innovation featuring large corporations such as Amazon.com, eBay, and Southwest Airlines as well as examples of breakthrough technology such as disk drives and hydraulic excavators. Table 1 lists examples of disruptive innovations mentioned in Christensen and Raynor's (2003) book *The Innovator's Solution: Creating and Sustaining Successful Growth*. The following section offers examples of disruptive innovations that fit under three main categories: (a) technological innovation, (b) catalytic innovation, and (c) business-model innovation.

Examples of Disruptive Innovation

This section offers three examples of disruptive innovations: (a) the advent of personal computers (PC), a technological innovation; (b) the appearance of online courses, a catalytic innovation; and (c) Southwest Airlines, a business-model innovation. The first example, the advent of personal computers, is an example of a catalytic innovation. The whole notion of disruptive innovation grew from studying technological products that replaced other products such as hard drives (1954 computer advance), hydraulic excavators, electric cars, ultrasound, and digital printing (Christensen, 1997). In the 1950s, IBM and other companies introduced the mainframe computer, which was at that time the most advanced computing machine. It was only available to customers who could afford paying hundreds of thousands of dollars. Consequently, IBM and other major players kept improving mainframe computers without paying attention to minicomputers, which were of interest to only a few customers.

Developers of minicomputers such as Digital Equipment Corporation started targeting consumers who were looking for a relatively inexpensive computer. Interestingly, Digital Equipment Corporation and other producers of minicomputers were later displaced by aggressive newcomers to the market such as IBM, Apple, and Dell which introduced affordable user-friendly computers, which targeted the mainstream customers (i.e., personal computers). Today, the cotemporary market is very broad from wrist size to wall size computers. Supply and demand varies throughout the market spectrum. Will laptops be replaced by tablets that are smaller, easier to carry, and cheaper? Apple offers smart keyboard and Apple Pencil for iPads, which make this tablets competitive, if not superior to many laptops' products.

The second example of disruptive innovation occurred in education, especially higher education, where online courses radically challenged face-to-face instruction. Online course delivery was a new technology that had broad social impact. Online universities appeared and many major universities had to adjust to the demands for convenience. Delivering course content over distance created a new market area and challenged ideological norms. It gave people in rural communities' equal opportunity to gain university degrees. Christensen et al. (2006) called it "catalytic innovation." According to Christensen et al. (2006, p. 1), "Catalytic innovations are a subset of disruptive innovation, distinguished by their primary focus on social change, often on a national scale." Online courses changed K-12 as well as higher education's traditional method of teaching (i.e., face-to-face).

Online courses have lowered the costs and the time associated with gaining an academic degree. It offers flexible scheduling for students and professors. There are various modes for the delivery of course instruction: Online classes can be hybrid (face-to-face and online), synchronized, and asynchronized classes. In synchronized classes, students and instructors interact with each other's during a scheduled time period, while with asynchronized classes interaction is more flexible. Although online courses can be considered an innovative method of teaching, they might not be categorized as a disruptive innovation. Since the 1990s, universities have offered online courses, but this technology did not allow online universities to usurp incumbents (i.e., top universities). Highly rated universities such as Stanford, Harvard, MIT, and Oxford were not radically affected by online courses, though they incorporated their use. These universities remained at the top of the rankings for higher education institutes. Christensen et al. (2018) admitted that the speed of disruption differs across industries and within a particular industry. Another example of "immune to

disruption" is the hotel industry. Although some new entrants such as Airbnb offer a cheaper and more convenient options for travel, major players such as Four Seasons, Marriott, and Hyatt hotels are still dominating the hotel market.

Finally, the third type of disruptive innovation is the business model. Although incumbents and entrants might possess the same technological capabilities, entrants disrupt established firms by introducing a new business model that targets low-end customers who are often neglected by incumbents. Perhaps the most extensively studied case of a business model innovation is Southwest Airlines. In 1971, when major players in the airline industry were competing against each other by developing their fleets (that is, better *business* and *first-class* services, new routes, and different plane size), Southwest Airlines started their business in Texas serving three cities. Southwest Airlines introduced a new business model, a low cost carrier, which focused on minimizing operation cost by: "(a) flying one model of plane rather than several, (b) a point-to-point route structure rather than hub-and-spoke, (c) one class of services rather than many, and (d) no meals, no assigned seating" (Raynor, 2011a, p. 31). What happened in this case of disruptive innovation is that Southwest Airlines offered a new business model, not a technology. This new business model attracted a segment of consumers who were looking for cheaper fares and did not mind landing in secondary airports. Today, Southwest Airlines is one of the largest Airline companies in the United States and the world.

The next section will review some of the criticisms that have been raised to challenge the theory of disruptive innovation. These challengers examined the predictive validity of the theory through a reexamination of the cases that Christensen and his colleagues reported.

Criticisms of the Theory of Disruptive Innovation

The theory of disruptive innovation received criticisms from experts in the fields of innovation and management. These criticisms can be classified into two categories: (a) experts who stressed distinguishing the different kinds of disruptive innovations, and (b) experts who challenged the theory's predictive validity.

Although the original theory of disruptive innovation mainly focused on disruptive technologies (Christensen, 1997), the theory evolved to include other kinds of innovations such as social (catalytic) innovation and business-model innovation. The problem, as indicated by a number of experts, was that the disruptive innovation theorists equated all three kinds of disruption. For example, Markides (2006) stressed the importance of distinguishing between (a) business model innovation, (b) technological innovation, and (c) radical product innovation.

Unlike disruptive technology, one of the elements that characterizes the business model innovation is that the entrants compete against incumbents in an *existing market*. Southwest Airlines, Amazon.com, Swatch, and online courses are examples of business model innovation. Amazon.com did not discover bookselling, rather, it introduced a new business model that challenged the traditional publishing houses distribution system. Amazon.com was one of the first to take advantage of the online shopping by featuring books at a lower price than book stores. The same economic incentive for the consumer inspired walk-in-clinics such as MinuteClinic and MedExpress, which offered less expensive healthcare services for uninsured people and for insured patients who did not have serious health problems. None of these examples of disruptive innovations invented a new market; they competed with incumbents within the same industries. The second feature that characterized the business model innovation is that it often uses a low cost value-chain, which make it difficult for established incumbents to respond.

The second kind of disruptive innovation is *radical* innovation. This kind of disruptive innovation occurs when a product of service creates a *new market*. According to Markides, "Radical innovations are disruptive to consumers because they introduce products and value propositions that disturb prevailing customer habits and behaviors in a major way" (p. 22). Airplanes, TVs, iPods, PCs, radios, and mobile phones are all examples of radical innovation. Most of the examples provided by Christensen (1997) represented radical technological disruptions where new entrants replaced incumbents; hydraulic excavators replaced steam shovel excavators, steam-powered ships replaced wind-powered ships, and USB flash drives replaced floppy disks.

The most serious wave of criticisms of the theory of disruptive innovation concerns the predictive power of the theory. King and Baatartogtokh (2015) comprehensively examined 77 cases reported by (Christensen, 1997; Christensen and Raynor, 2003). King and Baatartogtokh (2015) surveyed and interviewed at least one expert on each of the 77 cases.

In order to identify a product or service as a disruptive innovation, it should meet four criteria that describe the market place: (a) existing firms are involved in sustaining innovation in order to satisfy their customers' needs, and increase profits, (b) firms sustaining innovation overshoot the market with products or services that exceed customers' needs, (c) although existing firms have the capability to respond to the entrants, they ignore the disruption, and as a result, (d) they lose capital or market share (see Fig. 2; King and Baatartogtokh, 2015, p. 83).

Surprisingly, King and Baatartogtokh (2015) reported that not all cases cited by Christensen involved a firm in the process of "sustaining innovation" when a new entrant appeared. For example, slaughterhouses were disrupted by boxed beef not because they were focused on sustaining innovation, but because it would take time to adopt a new business-model. The same can be said about other cases of disruptive innovations where the process of sustaining innovation was not the real factor for the cause of the disruption.

Second, in the majority of cases, experts concluded that the emergence of a disruptive innovation was not the result of incumbents overshooting customers' needs. For example, internet search engines did not disrupt printed dictionaries market because publishers created dictionaries that exceeded customers' needs. The internet and search engines materialized and created new

Figure 2 Experts opinions on cases of disruptive innovations (King and Baartartogtokh, 2015, p. 83).

markets. The same can be said for the postal service, which has been disrupted by email; however, the postal services did not overshoot their market with a postal service that exceeded consumers' needs.

Third, Christensen and Raynor (2003) indicated that firms had the capability to respond to the rival's disruption, but they ignored them. In some examples of disruptive innovations, incumbents were incapable of responding to entrants because they were restricted by some laws and regulations (e.g., US airlines were not allowed to compete on price until 1979). Moreover, some firms were incapable of responding to the new disruption because they did not have the capability to compete in new businesses. For instance, incumbents in wood products were incapable of responding to plastic products because such a respond would require them to have the skills and tools to do so.

Finally, in many cases, entrants did not replace firms' products or services. Online banking services for example, did not replace the traditional banking services (Markides, 2006). Similarly, Southwest Airlines, online travel agencies, and Amazon.com did not replace incumbent airlines, traditional travel agencies, and bookstores respectively.

All in all, criticism might help enhancing the theory of disruptive innovation. Although the theory has a history of 20 years, and although many articles and books extensively discussed the theory, more rigorous research is needed to prove the theory's predictive power.

Conclusion

The term "disruptive innovation" has been widely used by experts and practitioners in different fields of study. In some cases, the term has been used incorrectly with regards to the theory of disruptive innovation. Christensen (2014) himself showed a concern of misuse of the term disruptive innovation: "The choice of the word disruption was a mistake I made 20 years ago and I never thought about the word disruption in the English language has so many connotations, that people would then flexibly use an idea, twist it, and use it to justify whatever they want to do in the first place." This assertion seems to be valid. Many people, experts or practitioners, use the term "disruptive innovation" without reading a single book about the theory. But this is not the only reason for misunderstanding of the theory. Another factor contributed to a misunderstanding is the lack of empirical studies on the theory.

That is not to say that there is not empirical investigations that tested the theory's predictability. For example, Raynor (2011b) conducted an experimental study to test the predictive power of the theory. Raynor (2011a) used Intel's New Business data for 48 businesses: only 5 businesses succeeded. In the first phase of the experiment, Raynor (2011b) randomly selected six cases and asked participants to predict the success rate. Participants correctly predicted only 10% of the cases. In the second phase of the experiment, participants received a training on the theory of disruptive innovation and then were asked to predict another set of cases. The results showed that the prediction rate increased from 10% to 15%. However, an increment of 5% is not overwhelming. The theory of disruptive innovation still has a long way to go to be empirically proven, however it still offers a good framework for researchers and industries by providing general guidelines for successful companies to anticipate and respond to possible disruptions. Granted, there will be more cases of disruptions in the future given the accelerated rate of knowledge and technology.

Glossary

Criterion problem There is no widely accepted criterion of creativity. If there were such a criterion, there might be no need for any other test or indicator of creativity. The criterion problem recognizes circularity: to find a good criterion of creativity, it must be tested against a good criterion of creativity.

Experiential bias Some divergent thinking tasks may allow respondents to draw from memory and experience rather than testing the cognitive capacity to generate ideas

Ideational flexibility The number of themes or categories within an examinee's or respondent's ideation

Ideational fluency The total number of ideas given by any one individual on any one divergent thinking exercise

Ideational originality The unusualness or uniqueness of an examinee's or respondent's ideas

Ideational pools These are constructed for each examinee or respondent and contain all of that individual's ideas. Judges can evaluate the pools rather than individual ideas. This means that judges have much more information and it less time-consuming and thus a cost-efficient method.

Structure of intellect J. P. Guilford's model, with 180 different kinds of intellectual processes and skills.

Background

J. P. Guilford is typically credited with first distinguishing between divergent thinking and convergent thinking. (The latter is involved whenever an individual thinks only about correct or conventional ideas and solutions. Convergent thinking is what is tested by most academic examinations and IQ tests.) Guilford also argued cogently for creativity being a natural resource and is credited with initiating the empirical research on the topic in the 1950s and 1960s. Certainly he was the first to be explicit about the value of divergent thinking, and he did most of the early research on the topic as he developed his structure-of-intellect (SOI) model. (This model contained 180 cells, many of which represented "divergent production," which was Guilford's own term for divergent thinking.) Several others before Guilford did recognize the importance of divergent thinking, even if they did not call it that. Alfred Binet, for example, had several open-ended questions that required his examinees to think divergently on his early tests of mental abilities. These tests were later adopted by Louis Terman of Stanford University and refined as the first IQ tests (i.e., the Stanford-Binet). Binet was working on his tests in the late 1800s, but again, his focus was mental ability, not creative potential.

Guilford's work represents the most comprehensive model of divergent thinking. His SOI did not fare well as a whole, but tests of divergent production have proven to be quite useful as estimates of the potential for creative thinking.

[☆] *Change History:* October 2019, Mark Runco updated the text throughout the article.

This article is an update of M.A. Runco, Divergent Thinking, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 400–403.

Several other theories are largely supportive of divergent thinking as an estimate of the potential for creative thought. In 1962, Sarnoff Mednick published his 'Associative Basis of the Creative Process,' and although he developed his own test, the Remote Associates Test (RAT), the associative theory presented by Mednick also supported and encouraged the use of divergent thinking tests. Importantly, the RAT may be verbally biased. Individuals who do well on tests of verbal ability often do well on the RAT, and persons who do poorly on tests of verbal ability tend to do poorly on the RAT.

In associative terms people respond to problems by generating ideas. Often one idea leads to another idea, which leads to another. Mednick discussed various ways that one idea could be associated with another idea, including acoustic similarity or functionality. Very importantly, he predicted that ideas found later in an associative chain are more likely to be original than those found early in that chain. This prediction has been supported a number of times, often with divergent thinking tests.

Some of the newest work on divergent thinking extends the associative idea to cognitive hyperspace. This is the label for a category of thought which is found by following one line of thought, and then turning 90° to a connected but perpendicular line of thought—and then turning again, and again, and again. In the natural environment there are only three dimensions (height, width, and depth) but in mathematics and various theoretical fields, hyperspace is possible. According to [Acar and Runco \(2015\)](#), some of the most creative ideas are found by exploring cognitive hyperspace instead of following one associative pathway.

The prediction from Mednick about 'remote associates' is very important in a practical sense because it suggests that individuals taking a divergent thinking test or working on a problem that will benefit from creative insight should make certain that they invest some time into the task. Otherwise remote and original ideas might not be found. It takes time to move from idea to idea and to eventually discover a remote associate. Educators and managers who would like to see their charges be creative should also be sure that the time provided is generous, and perhaps unrestricted.

A verbal bias was mentioned above, in the discussion of the RAT. Divergent thinking tests do not seem to suffer from a verbal bias but an experiential bias may come into play. After all, if an examinee is asked to "list things that move on wheels," and he or she grew up in an extremely isolated area where vehicles are uncommon or are all pretty much the same, that examinee will not have much information in long term memory. Another person, growing up in an area where most households own several vehicles, may have a huge advantage, at least in terms of available information. Yet that person may rely on long term memory and only think of things with which he or she had direct experience. When a test assesses experience and memory more than cognitive skill it is said to be *experientially biased*. At least one empirical study uncovered a bit of an experience bias in certain tests of divergent thinking, but the degree of bias apparently varies from test to test and from task to task. This takes us to a review of the different kinds of divergent thinking tests.

Tests and Example Questions

Guilford developed a large number of tests. As noted above, he was interested in the structure of the intellect and in distinguishing among 180 different kinds of thinking. (Most criticisms of Guilford's work are directed at his statistical methods, used to separate the different kinds of thinking. He often used a kind of factor analyses that required that subjective judgments be made by the psychometrician.) The three tests used most frequently by Guilford were probably Plot Titles, Consequences, and Alternative Uses. Plot Titles required the examinee to think of a title for a story that was presented. A modification of Titles, which is part of the rCAB battery, does not present a story but instead refers to famous movies or books, such as Titanic, or Romeo and Juliet, or the Hobbit, and then asks examinees to generate alternative titles. Guilford's Consequences test asks examinees to list the implications of some hypothetical situation (e.g., the world is suddenly covered with water). Alternative uses asks the examinee to generate uses of some common object (e.g., a coat hanger or brick). Versions of the Uses test are probably used more often than any other test of divergent thinking, though psychometric analyses indicate that it may be one of the least trustworthy in terms of reliability and internal consistency.

E. Paul Torrance developed the *Minnesota Tests of Creative Thinking* in the late 1950s (published in 1966). They contained a wide variety of tasks. They were revised in 1974 as the *Torrance Tests of Creative Thinking*. Examples include Just Suppose, Product Improvement, Ask and Guess, Unusual Uses, Thinking Creatively with Words, and Thinking Creatively with Pictures. Torrance's work was extended in various directions. This was a big step because it is informative to understand the creative potentials of very young children and because paper and pencil tests cannot be used with child at a young age. C. Woodruff Starkweather, for example, published materials describing the assessment of original ideation in preschool children. The divergent thinking of young children can be assessed, though not with paper-and-pencil tests. Instead three-dimensional forms are given to them and they are asked to talk about all the things the tangible object could be. A more recent method, piloted in 2018, shows children a 3D object on a computer screen and allows them to interact with it using a touch screen, so they can rotate the object, or zoom in or out, just to name three touch screen options. The children talk about what the object could be while they play with the touch screen, and the device records this narrative. It is transcribed with computer software and ideational fluency, originality, and flexibility scores are then extracted.

Various other batteries are available, in addition to those of Guilford and Torrance, including the rCAB, just mentioned, Roberta Milgram's *Tel Aviv Creativity Test*, the Williams Creativity Assessment Package, and a battery used in several seminal investigations by Michael Wallach. The last of these contains three verbal tests (Uses, Similarities, and Instances) and two Visual (or Figural) tests (Line Meanings and Pattern Meanings) and has proven to be enormously informative in several significant research projects, including those reported in *The Talented Student* and *Modes of Thinking in Young Children*. Wallach's tests and research set the stage for a large number of studies of divergent and creative thinking.

Divergent Thinking Indexes

Divergent thinking tests are scored in different ways, although most of the time a Fluency score and an Originality score are each calculated. These are the most common indices of divergent thinking. Fluency represents the number of ideas given. Originality is scored in a variety of ways. An objective score for originality might be calculated after determining the statistical infrequency of each idea. Highly infrequent ideas (e.g., those given by 5% of a particular sample) can be labeled original, each contributing to the Originality score. Unique ideas (i.e., given by only one person in any particular sample) are sometimes viewed as original. Uniqueness is more difficult in a larger sample, in which case unusualness scores should be used. Subjective scores have also been used, with judges rating the originality of ideas but, as is true of all scientific work, it is more objective to avoid raters and judges. There are good objective indices so there is no reason to use judges or raters with tests of divergent thinking. This is especially true because computerized systems have been developed for scoring divergent thinking tests (Acar and Runco, 2015; Beketayev & Runco, 2016; Dumas and Runco, 2018; Hass, 2017).

The next most common score is probably Flexibility. This is a very important score because high flexibility (a) precludes rigidity in problem solving and (b) guards against an artificially inflated originality score. Without a Flexibility score, one examinee could give a large number of unique ideas, all within the same category, and each would earn an Originality point even though they are not original compared to one another. If the examinee relies on one conceptual category but Flexibility is scored, the Originality score will be high but the low Flexibility score will indicate that Originality is inflated and not useful.

In 2004 Allan Snyder and associates developed and tested a new index of divergent thinking which they called the creativity quotient (CQ). It assumes that ideas produced may not be equally indicative of creative potential. Those in disparate semantic categories are therefore weighted heavily and contribute more than semantically similar ideas to the CQ. In some ways the CQ takes both fluency and flexibility into account at the same time.

The various indices of divergent thinking are frequently highly intercorrelated. This has led some researchers and examiners to conclude that only one score is necessary. Unfortunately, when one score is used, Fluency is usually the one chosen. It would make more sense to use Originality given that, in theories of creativity, originality is more important than fluency. Actually, it is probably best to use several scores because sophisticated statistical techniques (e.g., partialing unique variance and examination of interactions in canonical prediction equations) suggest that the different indices may each contribute useful information. In addition the newer computer scoring methods provide indices and scores that are not at all highly intercorrelated (Dumas and Runco, 2018).

The scoring of the Torrance divergent thinking tasks involves Fluency, Originality, and Flexibility, defined in a way that is comparable to the definitions given above. Torrance also recommended an Elaboration index for some of the tasks. This is based on the examinee's ideation within a category or theme. The examinee elaborates on one theme by following and extending it. A streamlined scoring system was developed for the Torrance tests in 1980. It uses a composite of the various indexes.

Not long ago Runco developed a scoring system that uses *ideational pools*. These pools are constructed for each examinee or respondent and contain all of that individual's ideas. Thus ideational pools contain a person's entire ideational output. The pools rather than individual ideas are then evaluated. There are at least two advantages of this system. First is the amount of information available to judges who may be involved in the scoring. Second is that only pools are evaluated, not each and every idea, so much less work is involved. Judges have more information because they see everything any one examinee or respondent did, not just a small portion of it (i.e., one idea). The judges can give one rating or judgment to each pool, rather than to each idea, so they need to invest much less time in the evaluations. This may preclude fatigue and allow them to concentrate better, and it requires less of their time. Still, recall here what was said above about the problems with judges (i.e., subjectivity and differences among groups of judges) and the possibility of using more objective measures that do not rely on judges.

Task Differences and Additional Tests

The various divergent thinking tests differ in significant ways. The Similarities test (e.g., how is a car like a jet?), for example, is relatively constrained and not quite as open-ended as some of the other tasks. The Instances test (e.g., "make a list of strong things") seems to be more open. The degree of openness is important because more openness is likely to allow more divergence and more originality, and possibly more flexibility as well. Also important is that openness is relevant to the order of test administration. If examinees have difficulty with divergent thinking, for example, which they might if they are in the midst of the 'fourth grade slump' or simply have had little or no practice at generating a large number of ideas, it might be best to start with Similarities. Because of its structure and relative constraint, it is likely to be the most familiar to examinees who are familiar with closed-ended academic tests but unfamiliar with open-ended tests. After working on Similarities, they might be presented with a slightly less constrained task, such as Uses, and then eventually a completely unconstrained task, such as Instances. This is essentially a "fading" method, from operant psychology, applied to the testing of divergent thinking.

Significantly, divergent thinking tasks can be used in a practical setting, as exercises. Here they are used to provide practice with and feedback on divergent and creative thinking, and very likely there is no actual test or assessment, just exercises. When divergent thinking tasks are used in this fashion, for practice, it is probably desirable that the skills or strategies students learn from divergent thinking generalize to the natural environment. For this reason realistic divergent thinking tasks might be given. These ask examinees to solve problems that might be encountered in the natural environment. These problems that are still open-ended and allow fluency, originality, and flexibility. Shawn Okuda developed a number of realistic tasks that are now part of the rCAB battery. Other

realistic tests are based on SWOT theory and allows research on the ideation of entrepreneurs. SWOT theory points to the strengths, weaknesses, opportunities, and threats to and of a business.

Examples of realistic tests are given below to bring home several of the points made above. The examples provided below are from tests designed for students.

Example Problem 1

Your favorite TV show was on last night. You had so much fun watching it that you forgot to do your homework. You are about to go to school this morning when you realize that your homework is due in your first class. Uh-oh ... what are you going to do?

For this problem, you could answer, "Tell the professor that you forgot to do your homework; try to do your homework in the car or bus on the way to school; ask your roommate, boyfriend, girlfriend, or classmate to help you finish your homework; do your homework tonight and turn it in the next time the class meets; or finish your homework first then show up late for class." There are many more answers to this problem, and all of them are legitimate.

Now turn the page, take your time, have fun, and remember to give as many ideas as possible for what to do about your forgotten homework.

Example Problem 2

Your friend Pat sits next to you in class. Pat really likes to talk to you and often bothers you while you are doing your work. Sometimes he distracts you and you miss an important part of the lecture, and many times you don't finish your work because he is bothering you.

What should you do? How would you solve this problem? Remember to list as many ideas and solutions as you can.

Example Problem 3

It's a great day for sailing, and your buddy, Kelly, comes to work and asks you if you want to go sailing. Unfortunately, you have a big project due tomorrow, and it requires a full day to complete. You would rather be sailing. What are you going to do? Think of as many alternatives that would allow you to go sailing as you can!

Advantages and Disadvantages

There is a trade-off with realistic tasks. They may motivate some examinees because they are realistic. Some examinees may not be all that interested in expending effort for tasks that are not realistic, such as listing uses for a brick. These examinees might be more interested in realistic tasks, such as listing excuses for not having completed homework! Then again, divergent thinking tasks are quite sensitive to the testing setting, conditions, and instructions, and Originality is the most likely when testing occurs under game-like conditions, when examinees are told that the tasks at hand are not tests and that there is no time limit, nor correct or incorrect answers. They can be told to have fun, take their time, and to be creative—and originality is very likely. And recall the need for time to find remote associates, which means that several minutes (e.g., five or six) should be given for each task. Ideally examinees should be told that they have as much time as they like. This will both allow remote associates to be found and let examinees know that the tasks are not like academic tests.

The trade-off mentioned just above arises because realistic tasks might be more constrained than the standard tasks, such as Instances or Uses. If this is the case the order of administration might be manipulated such that generalization to the natural environment is more likely. The order might begin with standard tasks, which are wide open, and then move to realistic tasks, which suggest that divergent thinking can be applied to problems found in the natural environment. This would be another way to use the fading method, which was mentioned earlier.

Importantly, the rCAB battery contains divergent thinking tasks that reflect an examinee's ability to generate problems (rather than solutions). These are, then, *problem generation* or *problem discovery* tasks rather than problem solving in response to presented problems. Problem generation tasks are open ended and can be scored for Fluency, Originality, and Flexibility. They can be used in conjunction with standard divergent thinking tasks to obtain a more general profile of an individual's ideational skills. Problem generation divergent thinking tasks are theoretically justified by the fact that creativity requires more than problem solving. Sometimes solving the problem is not the difficult thing; defining it might be more difficult. Problem generation divergent thinking tasks estimate what is often called problem finding ability.

The problem generation scores derived from divergent thinking tests may be important for certain clinical predictions. For example, the interaction between problem generation and problem finding was found to be highly related to suicide ideation. In particular, suicide ideation was related to the interaction between (high) Fluency scores on problem generation tasks and (low) Flexibility scores on problem solving tasks. This interaction was expected because it indicates that the individual is aware of many problems (as seen in his or her Fluency) but not aware of many different solutions (as seen in the low Flexibility). Significantly, this interaction between problem generation and problem solving was more strongly related to suicide ideation than depression measures, which are typically quite respectable predictors of suicide ideation.

There are other important aspects of creative problem solving, in addition to problem finding and solution (idea) generation. Solution evaluation is also very important. Some persons seem to know an original idea when they have one, while others do not. Runco and his students developed various reliable measures of idea evaluation and found that it can be reliably assessed and that idea evaluation is only moderately correlated with idea generation (Runco and Smith, 1992). More will be said about idea evaluation later in this entry.

Psychometric Issues

The most critical psychometric issue when testing divergent thinking—or any aspect of creative cognition—is discriminant validity. This relates to the distinctiveness of divergent thinking. Is it distinctive or does it overlap with other forms of ability? Is it related to IQ? Can we predict divergent thinking ability from measures of traditional intelligence?

Answers to these questions varied in the 1960s. In one seminal investigation Michael Wallach and Nathan Kogan administered divergent thinking tests under conditions that were dramatically different from the conditions typical of testing. They were the ones that first demonstrated the importance and advantages of game like testing conditions. They told the examinees – school children – that the divergent thinking tests were games, and they avoided referring to the tasks as tests. They allowed a great deal of time and were explicit about the need to generate a number of responses (rather than one correct response). Under these conditions the divergent thinking tests did display more than adequate discriminant validity. Previous research had administered divergent thinking tests under test-like conditions and discriminant validity was not good at all. It seems to require the right testing conditions.

The issue of discriminant validity is important in a practical sense because it indicates that divergent thinking tests provide information that would otherwise be unavailable. In behavioral terms it means that if schools rely on tests of traditional ability they will overlook children who have outstanding divergent thinking abilities (but only moderate or even low IQs and academic aptitude).

The relationship of divergent thinking with IQ and traditional intelligence seems to vary at different levels of ability. There may even be a threshold of intelligence that is necessary for creative ideation. This would make sense because some basic information processing capacity is necessary for associative and divergent thinking. Additionally, many tests of divergent thinking require that the examinee has some basic knowledge, and that too suggests a modicum of traditional intelligence. Logically creative problem solving probably depends on both creative cognitive capacity but also strategy and knowledge.

The ‘threshold theory’ suggests that some traditional ability is necessary for effective divergent thinking. The early estimates were an IQ of approximately 120, but this figure is probably just about meaningless, in part because the average IQ in the population is on the rise. Then there are the questions about the validity of the IQ. Still, the concept of a threshold does make good sense, even if we cannot pinpoint a specific IQ.

The threshold may be viewed graphically, as would be the case if divergent thinking scores were plotted as a function of IQ levels. When this is done a triangle of data points appears in the bivariate scatterplot. The top of the triangle is pointed at the origin of the graph, with the scatter of data spreading as IQ levels increase. If that same scatterplot is bisected perpendicularly to the *X* axis (and at the hypothetical threshold) and also bisected perpendicularly to the *Y* axis, four quadrants are formed. Empirical studies find some persons in the first quadrant, with low divergent thinking and low IQ. There are also persons with high IQs and low divergent thinking. There are a few persons with high divergent thinking and high IQ, but no one with low IQ and high divergent thinking. This triangular distribution supports the idea of a minimum threshold of IQ which is necessary but not sufficient for divergent thinking. Research from Runco and Albert (1986) and, more recently, from Jauk et al. (2013) suggests that the threshold may vary from index to index, with one threshold for fluency and another for originality. Correlations also vary depending on the measure of convergent thinking used.

There are persons with high IQs and low divergent thinking, which again supports the discriminant validity of the divergent thinking tests. It also suggests that individuals who are extremely good at the convergent thinking and memorization required for exceptional IQs may be at a serious disadvantage for divergent thinking and creative thinking. They may only be able to think of conventional ideas and are unable to generate original ideas.

A second critical issue is that of the predictive validity of divergent thinking tests. Here again, results have been quite varied. This is not much of a surprise, however, given that creativity can be expressed in so many different domains. Moreover, divergent thinking tests do not guarantee actual performance any more than any other controlled assessment offers any guarantees. As noted above, divergent thinking tests are estimates of the potential for creative thought, and actual creative problem solving requires other things (e.g., attitude, problem finding, idea evaluation, motivation).
